manifestations is a breach in the vascular and airway barrier function,¹⁹ with rapid recruitment of circulating inflammatory cells to the lung. Inflammation is found in the peripheral airways of all smokers even before COPD is established and consists of mononuclear cell infiltrates and clusters of macrophages in the walls of the respiratory bronchioles.¹⁵ These lesions develop initially in the absence of any significant tissue destruction or fibrosis and may be reversible. An inflammatory process involving T lymphocytes and macrophages has also been described in the large airways of smokers with chronic bronchitis.²⁰ Acute cigarette smoke exposure can result in tissue damage with degradation of extracellular matrix proteins and lipid peroxidation products.²¹

These early inflammatory changes in the airways likely represent the nonspecific innate immune response to airway injury from tobacco smoke. It is unclear why some smokers

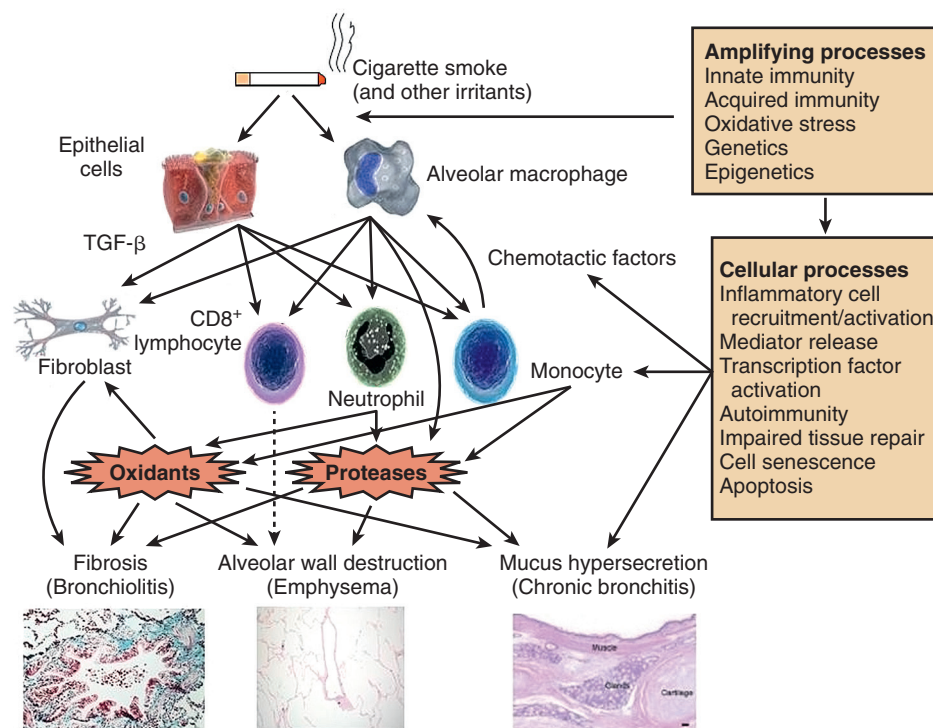

Figure 43-3 Overview of the pathogenesis of COPD. Cigarette smoke activates macrophages and epithelial cells to produce chemotactic factors that recruit neutrophils and CD8 cells from the circulation. These cells release factors that activate fibroblasts, resulting in abnormal repair processes and bronchiolar fibrosis. Imbalance between proteases released from neutrophils and macrophages and antiproteases leads to alveolar wall destruction (emphysema). Proteases also cause the release of mucus. An increased oxidant burden resulting from smoke inhalation or release of oxidants from inflammatory leucocytes causes epithelial and other cells to release chemotactic factors, inactivates antiproteases, directly injures alveolar walls, and causes mucus hypersecretion. Several processes are involved in amplifying the inflammatory responses in COPD.

develop structural abnormalities that eventually lead to clinically detectable COPD, whereas others continue to show an inflammatory infiltrate but maintain otherwise normal airways and lung parenchyma and only mild functional changes that do not become clinically relevant.

Smoking cessation alters the inflammatory response in the lungs in asymptomatic smokers and in patients with COPD.⁵ Cross-sectional studies of the effects of smoking cessation^{22,23} show that ex-smokers have less goblet cell hyperplasia and less squamous cell metaplasia in the small, but not the large, airways. Smooth muscle mass in the peripheral and central airways, fibrosis, deposition in the airway wall, fibrosis of the peripheral airways, and the degree of alveolar destruction is not different in asymptomatic ex-smokers and current smokers, nor is the inflammatory response different. There are limited longitudinal studies of the effects of smoking cessation on the inflammatory response in the lungs.^{5,24} Large airway inflammation indicating chronic bronchitis decreased by 3 months and disappeared after 6 months of smoking cessation. Inflammation as assessed in sputum and from bronchial biopsies decreased 1 year after smoking cessation in asymptomatic smokers.²⁴

INFLAMMATION IN THE LUNGS IN COPD

Studies of lung or bronchial biopsies and induced sputum have shown that lung inflammation is present in all cigarette smokers. However, an enhanced or abnormal inflammatory response to inhaled particles or gases, beyond the

normal protective inflammatory response, is a characteristic feature of COPD and has the potential to produce lung injury. Both the innate and adaptive inflammatory and immune responses are involved in the lung inflammation in COPD patients. Recent studies have characterized the inflammation in the lung in COPD in terms of its type, site, degree, and relationship to severity of disease.

CELLULAR INFLAMMATORY RESPONSES

Bronchial biopsies from smokers with symptoms of chronic bronchitis who have not developed airflow limitation demonstrate that the airway epithelium remains intact; however, the epithelium shows squamous metaplasia and there is an increase in goblet cells.²⁵ In contrast to asthma, the epithelial reticular basement membrane is not thickened.²⁶ In patients with mild to moderate COPD, there is an increase in inflammatory cell infiltration in the central airways, compared with nonsmokers or smokers who have not developed the disease.²⁷ In the bronchial epithelium and submucosa in COPD patients,²⁵ monocytes are the major cell with scanty neutrophils.²⁷ Of the monocyte component, T lymphocytes predominate, mainly CD8⁺ cells (T-cytotoxic lymphocytes) and macrophages (CD68⁺ cells)²⁸ (eTable 43-1), in contrast to asthma, in which CD4⁺T-helper (T helper 2) lymphocytes predominate.²⁹ Thus, the ratio of CD8⁺/CD4⁺ increases in COPD.^{20,28} Morphometric analyses of bronchial biopsies show that the ratios of CD8⁺/CD4⁺ T cells are 1.3, 11.8, and 4.3 (mean/mm³) in healthy smokers,

stable chronic bronchitis, and exacerbated chronic bronchitis, respectively.²⁵ CD8⁺ T cells are also observed in the sputum,^{30,31} bronchial glands,³² bronchial smooth muscle,³³ and around lymphoid follicles.¹⁶ It has been suggested that the presence of increased CD8⁺ T lymphocytes differentiates between smokers with and without COPD and that there is a correlation between T-cell numbers, the smoking history, the amount of alveolar destruction, and the severity of airflow limitation.^{25,28} However, smokers with normal lung function also show an increased number of CD8⁺ cells compared with control nonsmokers.²⁰

The mechanism by which CD8⁺ T lymphocytes accumulate in the airways in COPD is not fully understood. There is increased expression of CXCR3 on T cells in the peripheral airways in COPD patients. CXCR3 is a receptor activated by *interferon-inducible protein* (IP)-10, and the expression of IP-10 itself is increased in bronchiolar epithelial cells. This could contribute to the accumulation of CD8⁺ cells, which preferentially express CXCR3. Circulating CD8⁺ cells are also increased in number in COPD patients.³⁴ These changes suggest chronic immune stimulation. CD8⁺ cells have a well-recognized role in respiratory viral infections, contributing to viral clearance. It may be that chronic colonization of the lower respiratory tract of COPD patients by bacterial and viral pathogens is responsible for this enhanced inflammatory response.⁷ An increase in B lymphocytes and in bronchial-associated lymphoid tissue in small airways also is present as the disease progresses,¹⁶ suggesting an adaptive immune response. It is possible that cigarette smoke damages airway cells, creating new autoantigens that drive the immuno-inflammatory response.³⁵

The role of T cells in the pathogenesis of COPD is not fully understood. CD8⁺ cells have the potential to release *tumor necrosis factor* (TNF)- α , perforins, and granzymes. CD8⁺ T lymphocytes isolated from the sputum of smokers are activated and release perforin.³⁰ In addition, CD8⁺ cells activate the Fas/Fas ligand apoptotic pathway and there is an association between CD8⁺ cells and alveolar epithelial cell apoptosis in subjects with emphysema.

Increased numbers of activated neutrophils are found in both *bronchoalveolar lavage* (BAL) fluid and sputum from patients with COPD.^{27,37} The mechanism of neutrophil passage into the airway lumen in COPD is not entirely clear. Cigarette smoking is known to increase circulating neutrophil counts and to cause sequestration of neutrophils in the lung capillaries¹⁸ by decreasing their deformability. Cigarette smoke also has a direct stimulatory effect on granulocyte production in the bone marrow, possibly mediated by *granulocyte macrophage colony-stimulating factor* (GM-CSF) and G-CSF released from macrophages.³⁸ Once sequestered in the pulmonary microcirculation, it is possible that an imbalance between proinflammatory and anti-inflammatory cytokines may result in neutrophil migration into the airspaces. Expression of anti-inflammatory mediators, such as *secretory component* (SC), club cell (Clara) protein (CC16), and *interleukin* (IL)-10, are decreased in the airway lumen of smokers with COPD,^{39,40} whereas cytokines, such as IL-8 and *monocyte chemoattractant protein* (MCP)-1, which promote the chemotaxis of neutrophils and monocytes, respectively, and TNF- α , which activates adhesion molecules, are increased.⁴¹⁻⁴³ Up-regulation of E-selectin and *intercellular adhesion molecule* (ICAM)-1 on submucosal vessels and on

bronchial epithelium of subjects with COPD⁴² suggests that these adhesion molecules may be involved in the recruitment of neutrophils from the circulation and their migration from bronchial subepithelial capillaries into and through the epithelium to enter the airway lumen. The airway epithelium is a rich source of the cytokines/chemokines that recruit both neutrophils and macrophages into the airspaces. Many of these cytokines/chemokines are overexpressed in COPD.⁴³ IL-6, IL-1 β , TNF- α , *growth-related gene*- α (GRO- α)/*keratinocyte-derived chemokine* (KC, CXCL1), MCP-1, and IL-8 are increased in the sputum in COPD patients and the bronchiolar epithelium overexpresses MCP-1, its receptor CCR2, MIP1 α , and IL-8.

The role of neutrophils in the pathogenesis of COPD is not entirely clear. Neutrophils can secrete serum proteinases, including neutrophil elastase, cathepsin G, and proteinase 3, as well as *matrix metalloproteinase* (MMP)-8 and MMP-9. These proteases may contribute to alveolar destruction and are also potent stimuli of mucus secretion. Relationships have been shown between circulating neutrophils and the decline in FEV₁.⁴⁴ Similarly, neutrophil numbers in bronchial biopsy specimens and induced sputum are related to disease severity⁴⁵ and the rate of decline in lung function.⁴⁶

There is a 5- to 10-fold increase in the numbers of macrophages in the airways, lung parenchyma, and BAL in patients with COPD. Macrophage numbers in the airways correlate with the severity of the airflow limitation in COPD.⁴⁷ Cigarette smoke activates macrophages to release inflammatory mediators, including TNF- α , IL-8, and other CXC chemokines, MCP-1, leukotriene B₄, and *reactive oxygen species* (ROS). Macrophages also secrete proteases, including MMP-2, MMP-9, MMP-12, cathepsins K, L, and S, and neutrophil elastase taken up from neutrophils. Macrophages from COPD patients are more activated, secrete more inflammatory proteins, and have greater elastolytic activity when compared with macrophages from normal smokers; macrophage activation is further enhanced by exposure to cigarette smoke.^{47,48} Increased numbers of macrophages in the lungs of COPD patients and smokers may result from increased recruitment of monocytes from the circulation in response to monocyte chemotactic chemokines such as MCP-1, which is increased in sputum and BAL in patients with COPD.⁴⁹ CXC chemokines also act as chemoattractants to monocytes. The concentration of CXCL1 is markedly increased in sputum and BAL from patients with COPD. Furthermore, monocytes from patients with COPD show a greater chemotactic response to CXCL1 than the monocytes from normal smokers and nonsmokers.⁵⁰

Dendritic cells are present in increased numbers in the airways and alveolar walls of smokers.⁵¹ The role of dendritic cells in COPD is not yet defined, but the cells are likely to have an important role in the innate and adaptive immune responses in COPD.

Cigarette smoke activates airway epithelial cells to produce inflammatory mediators, including TNF- α , IL-1 β , GM-CSF, and IL-8. The epithelium in the small airways may be an important source of *transforming growth factor* (TGF)- β , which may induce local fibrosis.⁵² Epithelial cells can also secrete antioxidants and antiproteases and transport immunoglobulin- α and thus may be involved in adaptive

immunity. Cigarette smoke may impair these innate and adaptive immune responses of the airway epithelium and increase the likelihood of infection.

The expression of many of the inflammatory mediators implicated in the inflammatory response in the lungs in COPD is controlled by the transcription factor *nuclear factor* (NF)- κ B. NF- κ B is up-regulated in alveolar macrophages in patients with COPD and in airway cells in patients with mild/moderate COPD in comparison with control nonsmokers.^{53,54} Up-regulation of NF- κ B in lung cells in COPD may be a key molecular mechanism in the ongoing inflammation in the airways. Epigenetic modifications may also contribute to the enhanced inflammation in the lungs in COPD. *Histone deacetylase* (HDAC) 2 has been shown to be reduced in lung cells of subjects with COPD; a reduction of HDAC would allow increased acetylation of histone residues on DNA, a greater unwinding of DNA, and a greater access of transcription factors such as NF- κ B that up-regulate proinflammatory genes.

In general, with increasing severity of COPD there is a further increase in the inflammatory response. There is an increase in the number of neutrophils and macrophages in severe disease and a decrease in T lymphocytes (CD3⁺ cells) (see eTable 43-1). There appears to be a shift in the cellular type in severe disease toward cells with a phagocytic and proteolytic role in the bronchial tissues (see eTables 43-1 to 43-3).

CYTOKINES AND CHEMOKINES⁵⁵

In patients with severe emphysema, lymphocytes in the lungs strongly express TH1 cytokines and secrete high levels of *interferon* (IFN)- γ , CCR5, and CXCR3. In addition, they show increased expression of CXCR3 ligands, *monokine induced by interferon gamma* (MIG), and IP-10.⁵⁶ This polarization of alveolar lymphocytes toward the TH1 phenotype predominates in severe emphysema.

TNF- α has also been implicated in cigarette smoke-induced emphysema. Increased levels of TNF- α are present in the airways in cigarette smokers.³⁶ Animals that overexpress TNF- α show evidence of emphysema and an exaggerated alveolar inflammatory response,⁵⁷ while TNF receptor knockout mice demonstrate significant protection against cigarette smoke-induced emphysema.⁵⁸ With respect to emphysema, TNF- α stimulates MMP synthesis by alveolar macrophages.⁴⁷ Cultured macrophages exposed to cigarette smoke extract release TNF- α ⁴⁷ and, in addition, circulating TNF- α soluble receptors p55 and p75 are significantly increased in COPD patients compared with healthy controls.⁵⁹ In animal studies, absence of TNF- α receptor type 2 was associated with reduced inflammatory responses in terms of neutrophil, macrophage, CD4 and CD8 cell influx, and protection against cigarette smoke-induced emphysema.⁶⁰

IL-1 β may also play a role in the development of emphysema. In animal models, lung-specific induction of human IL-1 β resulted in emphysema,⁶¹ whereas inhibition with IL-1 β antibody reduced alveolar macrophage influx into the airspaces following cigarette smoke exposure.⁶² Furthermore, double IL-1 receptor and TNF- α receptor knockout mice are protected against elastase-induced emphysema.⁶³

Inflammation, Airway Remodeling, and Airflow Limitation

The peripheral airways (bronchioles < 2 mm in diameter) are the major site of increased resistance to airflow in COPD.^{14,64} The main pathologic lesions in the peripheral airways include increased number of inflammatory cells (see Table 43-1 and eTable 43-2) and structural changes, such as epithelial goblet cell metaplasia, airway wall fibrosis, and smooth muscle hypertrophy.^{25,65,66} The increase in the thickness of the airway wall, inflammation, fibrosis, and smooth muscle hypertrophy will encroach on the lumen and reduce airway diameter; increased wall thickness may also uncouple the airways and the surrounding lung parenchyma, thereby reducing the elastic force that opposes bronchiolar smooth muscle contraction and promoting airway closure. Airway wall inflammation can also contribute to the destruction of alveolar-bronchiolar attachments, producing deformation and narrowing of the airway lumen. This is supported by the observation that, in smokers, the destruction of alveolar attachments correlates with the degree of inflammation in peripheral airways.⁶⁷

Increased goblet cell metaplasia and subsequent hyperplasia in the small airways of smokers may also limit airflow.⁶⁵ The goblet cell may contribute to the increased peripheral airway resistance by producing mucus at a site where it is not normally produced, leading to a marked increase in the surface tension of the airway lining fluid. This would lead to instability of the peripheral airways, facilitating their early closure during expiration. The increase in goblet cells in the peripheral airway epithelium of smokers is associated with an increased number of neutrophils.⁶⁵ Because neutrophil elastase is a potent secretagogue,¹⁰ the colocalization of neutrophils and goblet cells within the epithelium in COPD may result in increased secretion of mucus by goblet cells.

In smokers with COPD, CD8⁺ T lymphocytes are increased not only in central airways but also in peripheral airways and in the lung parenchyma⁶⁸ (see eTable 43-2). CD8⁺ cytotoxic T cells are thought to play a role in the rapid resolution of acute viral infections that are frequent in patients with COPD. The observation that people with frequent childhood respiratory infections are more prone to develop COPD⁶⁹ supports the role of current and latent viral infections in this disease.^{70,71} In response to repeated or persistent viral infection, it is possible that an excessive number of CD8⁺ T lymphocytes may be recruited and damage the lung in susceptible smokers, possibly through the release of TNF- α and perforins.^{72,73} Conversely, it is also possible that CD8⁺ T lymphocytes can damage the lung directly, even in the absence of viral infection. It has been hypothesized that the CD8⁺ cytotoxic T cell and other inflammatory cells accumulate in response to an autoantigen.^{35,74}

Inflammatory changes appear to target the peripheral airways and alveoli. A comparison of the central and peripheral airways shows that the total number of inflammatory cells is increased in the peripheral airways (<3 mm diameter) in patients with chronic bronchitis with normal lung function, compared with control smokers (see eTable 43-2). Some studies have shown an increase in total leukocytes and in CD8⁺ cells in the peripheral airways of patients with mild/moderate COPD in comparison with control

smokers.⁷⁵ Studies of tissue obtained from lung volume reduction surgery in patients with severe COPD have shown an increase in total leukocytes and in CD4⁺ and CD8⁺ lymphocytes in both the peripheral airways and the lung parenchyma.¹⁶ In contrast, smokers with normal lung function show an increased number of macrophages and T lymphocytes in lung parenchyma compared with control nonsmokers, with no changes in CD4⁺ and CD8⁺ cells. In patients with mild to moderate COPD, there is an increase in CD8⁺ cells in the alveolar septa compared with control nonsmokers, with no change in the numbers of neutrophils, macrophages, or CD4⁺ cells.⁷⁵

The inflammatory response in the peripheral airways may play a role in the fibrosis that characterizes the small airways in patients with moderate/severe COPD.⁷⁶⁻⁷⁸ As the disease progresses, small airways develop increased thickness and enhanced inflammatory infiltrate by neutrophils, macrophages, and T lymphocytes (CD4⁺ and CD8⁺ T cells), and B lymphocytes. Lymphoid follicles also accumulate within the walls of the bronchioles, and the lumen of these airways are often obliterated by mucus.^{16,17,78} A number of mechanisms have been proposed to link inflammation and small airway remodeling. *Fibroblast growth factor* (FGF) and *FGF receptor* (FGFR) signaling appear to be associated with airway vascular remodeling in chronic bronchitis. In studies of lung tissue from COPD, FGF1 and its receptor FGFR1 are detected by immunohistochemistry in vascular and airway smooth muscle and in airway epithelial cells.⁷⁹ FGF1 and/or FGF2 increase the mRNA levels of FGFR1 and induce cellular proliferation of cultured human airway smooth muscle cells.⁸⁰ Smokers with COPD show increased expression of FGF in central airways, predominantly due to enhanced expression in the bronchial glands, suggesting that FGF may also have a role in promoting mucus hypersecretion in smokers.⁸¹

The pattern of cytokine profile and chemokine receptor expression has been investigated in the peripheral airways in COPD. CD8⁺ T cells in the peripheral airways in COPD are associated with IFN- γ and express CXCR3,⁸² a chemokine receptor that is thought to be preferentially expressed on TH1 cells. Moreover, CXCR3 expression is associated with the expression in the epithelium of its ligand CXCL10. This suggests that the CXCR3/CXCL10 axis may be involved in the recruitment of TH1 cells into the peripheral airways of smokers with COPD. These studies also showed that the interaction of CXCL10 with CXCR3 drives the release of macrophage MMP12 by macrophages. MMP12 is a potent elastolytic enzyme, which can cause lung tissue destruction. These data suggest a possible mechanism by which TH1 lymphocytes can drive the progression of small airway and emphysematous destruction, thus relating the inflammation in peripheral airways to surrounding alveoli. Studies also indicate that differences in gene expression in the small airways and surrounding lung parenchyma may result preferentially in fibrosis of small airways but in loss of alveolar cells in the lung parenchyma, resulting in emphysematous destruction.⁸³

MUCUS HYPERSECRETION

Mucus forms a film that coats the airway epithelium and is propelled from the periphery of the lung to the upper

airways by the coordinated movement of cilia. The main constituents of the mucus layer are mucus glycoproteins (mucins), water, and peptides. Mucus plays a key role in the clearance of foreign material and infectious agents and has important antioxidant properties. In chronic bronchitis, there is an increase in mucus in the airways, resulting from increased production of mucins and increased secretion from goblet cells.

Mucus production and secretion in COPD is regulated by multiple cellular and molecular mechanisms. Goblet cells express MUC5AC and MUC2 while glandular mucosal cells express MUC5B, MUC8, and MUC9.⁸⁴ Enhanced expression of MUC5B has been shown in the bronchiolar epithelium of COPD patients.⁸⁵ A number of stimuli such as neutrophil elastase, *lipopolysaccharides* (LPSs), IL-1 β , TNF- α , cigarette smoke, and oxidative stress cause goblet cell metaplasia and mucus hypersecretion.⁸⁶ Neutrophil elastase increases MUC5AC mRNA levels by enhancing mRNA stability.⁸⁷ LPS also induces MUC5AC expression in animal models, associated with neutrophil infiltration⁸⁸ and increased expression of MMP9.⁸⁹

Signaling pathways initiated by *epidermal growth factor* (EGF) receptor phosphorylation, which can be induced by cigarette smoke-derived oxidative stress, EGF, or TGF- α , also play an important role in mucin production in airway epithelial cells.⁸⁶ ROS can activate the serine protease tissue kallikrein, which can then cleave the transmembrane precursor of EGF.⁹⁰ Cigarette smoke produces ROS, also resulting in *vascular endothelial growth factor receptor* (VEGFR) activation and mucus production by activation of the *TNF α converting enzyme* (TACE), resulting in loss of TGF- α in airway epithelial cells.⁹¹ Acrolein, a component of cigarette smoke, can also induce MUC5AC expression created by ligand/dependent activation of EGFR and mediated by TACE and MMP9.⁹² In addition, ROS derived from cigarette smoke can activate an Src-dependent signaling cascade and trigger transcriptional regulation of MUC5AC mediated by binding of the activator protein-1 response element by JunD and Fra-2.⁹³ Moreover, cigarette smoke extract has been shown to synergize with LPS or TNF- α in the induction of MUC5AC expression, suggesting a potential amplification by cigarette smoke and inflammatory stimuli relevant to the pathogenesis of COPD.⁹⁴ A number of transgenic mice experiments have begun to unravel the complex interplay between inflammation, oxidative stress, and growth factors in the development of mucus hyperplasia. These studies suggest that CD4⁺ Th2 cells and the cytokine network including IL-4, IL-10, and IL-13 play a crucial role in the development of goblet cell hyperplasia/metaplasia.⁹⁴⁻⁹⁷

PROTEASES/ANTIPROTEASES

A protease/antiprotease imbalance, leading to the breakdown of connective tissue components, particularly elastin, has been considered to be the critical mechanism in the pathogenesis of emphysema in smokers. This concept developed from studies showing the development of early-onset emphysema in patients deficient in the major *anti-elastase* α_1 -antitrypsin (A1AT)⁹⁸ and from animal studies showing the development of emphysema in response to the instillation of proteolytic enzymes.⁹⁹ Pallid mice, which have

decreased A1AT levels, develop emphysema earlier on exposure to cigarette smoke than mice with normal A1AT levels.^{100,101} Furthermore, mice lacking neutrophil elastase are protected from chronic cigarette smoke-induced emphysema.¹⁰²

Elastin is the principal component of elastic fibers and is secreted from several cell types as a precursor, tropoelastin. These tropoelastin molecules become aligned in the extracellular space on microfibrils. Under the action of lysyl oxidase, the lysine residues in tropoelastin are modified, causing the tropoelastin monomers to cross-link and form larger, insoluble elastin polymers. Because the cross-links, known as *desmosines*, are unique to elastin, they have been used as a marker of elastin degradation. Elastin turnover is minimal in normal subjects; thus, breakdown products should not be detectable. However, desmosine and elastin peptides are elevated in smokers and patients with COPD.¹⁰³ In addition, studies have shown that the annual rate of decline in FEV₁ in a group of smokers correlated positively with urine levels of desmosine.¹⁰⁴

Elastin is an important target for proteolytic enzymes, and its destruction results in loss of elasticity in the lung parenchyma. Together with the destruction of elastin, inactivation of antiproteases is central to the protease/antiprotease imbalance hypothesis. Early studies showed that the function of A1AT was reduced by about 40% in smokers, compared with nonsmokers.¹⁰⁵ This “functional A1AT deficiency” was thought to result from inactivation of A1AT by oxidants in cigarette smoke. However, most of the A1AT in cigarette smokers remains active and is therefore still capable of protecting against the increased protease burden. Studies assessing the function of A1AT in either chronic or acute cigarette smoking have not been definitive. Only a transient and nonsignificant fall in A1AT activity has been measured in BAL 1 hour after smoking.¹⁰⁶ Thus, the hypothesis that the major event is an imbalance between an increased elastase burden in the lungs and a “functional deficiency” of A1AT, due to its inactivation, is an oversimplification.

There are increased numbers of neutrophils and macrophages in the airspaces in chronic smokers, which may increase the elastase burden by the release of elastase from activated neutrophils. In support of this, neutrophils isolated from patients with emphysema show greater elastase-induced fibronectin degradation in vitro than cells from control subjects matched for age and smoking history.¹⁰⁷ Other studies have invoked a contributory role for other antiproteases, such as antileukoprotease, or more subtle changes (e.g., a decrease in the association rate constant of A1AT for neutrophil elastase, which may contribute to elastin degradation).

There is also evidence that an abnormality in elastin synthesis and repair may be involved in the pathogenesis of emphysema. In an animal model of elastase-induced emphysema, treatment with retinoic acid restored normal alveolar architecture.¹⁰⁸ These studies in adult rats (which have continued lung growth throughout their adult life, in contrast with humans) provide some evidence that the destructive process in emphysema, which was always considered irreversible, may be capable of repair. However, human studies of retinoic acid have not shown any evidence of repair of emphysema.¹⁰⁹

In addition to serine proteases, cysteine proteases (cathepsins) may have a role in the pathogenesis of COPD. Cathepsin-L has been detected in BAL from patients with emphysema,¹¹⁰ and alveolar macrophages in patients with COPD secrete more cysteine proteases than macrophages from normal smokers or nonsmokers.¹¹¹

Matrix metalloproteases (MMPs) are a group of at least 20 proteolytic enzymes that have a role in tissue remodeling and repair associated with normal development and inflammation, by degrading collagen, laminin, and elastin. They are characterized in distinct subclasses depending on their substrate specificity, amino acid similarity, and identifiable sequence molecules. The subclasses are collagenases (MMP1, 8, 13), gelatinases (MMP2, 9), stromelysin S (MMP3, 10, 11), membrane-type MMP14–MMP25), matrilysin (MMP7), and macrophage metalloelastase (MMP12).¹¹² The major inhibitors of MMPs are alpha-2 macroglobulin and the *tissue inhibitor of metalloproteases* (TIMP) family.

There is substantial evidence for a role of MMPs in the pathogenesis of COPD.¹¹³ Several studies have shown increased expression of several MMPs in the lungs of COPD patients. MMP12 protein has been observed in sputum, BAL, bronchial biopsies,^{113,114} and peripheral lung tissue in patients with severe emphysema.¹¹⁵ Increased concentrations of MMP1 (collagenase) and MMP9 (gelatinase B) are present in BAL from patients with COPD,^{116,117} and there is increased activity of MMP9 in the lung parenchyma of patients with emphysema.¹¹⁸ MMP12 mRNA can be induced by exposure of human bronchial epithelial cells to cigarette smoke extract or cytokine mix (TNF- α and IFN- γ).^{119,120} Alveolar macrophages from smokers express more MMP9 than those from normal subjects, and there is an even greater increase in patients with COPD.⁴⁷

There is considerable evidence from experimental models to link MMP12 and the development of emphysema. Increased MMP12 expression was present in alveolar macrophages after smoke exposure in C57BL/6 mice,¹²¹ and animal models have shown that cigarette smoke does not induce emphysema in mice lacking MMP12.¹²² MMPs are also known to activate the latent form of TGF- β . In mice lacking the integrin α V β 6, there is a failure to activate TGF- β , and these animals do not develop age-related emphysema, which can be overcome by overexpression of TGF- β 1.¹²³ These data suggest that TGF- β may down-regulate MMP12 under normal conditions and that the absence of TGF- β results in excessive MMP12 production and emphysema. Although MMP9 and MMP2 both degrade elastin and are both expressed in COPD lungs, the role of these MMPs in the pathogenesis of COPD remains unclear.

OXIDANTS/ANTIOXIDANTS IN COPD

Cigarette smoke is a complex mixture of more than 4700 chemical compounds, including high concentrations of free radicals and other oxidants.¹²⁴ The oxidant burden in lungs may be further enhanced in smokers by the increased numbers of neutrophils and macrophages in the alveolar space that release increased amounts of oxidants, such as oxygen and H₂O₂.¹²⁵ Other sources of ROS are those generated through normal cellular processes in the lungs, such as those produced by normal cellular respiration, or by inhalation of air pollutants, such as particulate pollution.

A delicate balance exists between the toxicity of oxidants and the protective effects of intracellular and extracellular antioxidant defense systems, which are critically important for the maintenance of normal pulmonary cellular functions. A shift of the oxidant/antioxidant balance in favor of oxidants is known as oxidative stress. There is now considerable evidence of increased oxidative stress in smokers and patients with COPD.¹²⁶

All tissues are vulnerable to oxidant damage but, by virtue of its direct contact with the environment, the airspace epithelial surface of the lung is particularly vulnerable. Injury to the epithelium, manifested as an increase in airspace epithelial permeability, may be an important early event following exposure to cigarette smoke.¹²⁷ Extracellular and intracellular glutathione, an antioxidant, appears to be critical to the maintenance of epithelial integrity following exposure to cigarette smoke. This was shown in studies in which the increased permeability of epithelial cell monolayers in vitro, and in rat lungs in vivo, following exposure to cigarette smoke condensate, was associated with profound changes in the homeostasis of glutathione.^{128,129} These in vitro and animal studies are paralleled by human studies demonstrating increased epithelial permeability in chronic smokers compared with nonsmokers, with a further increase in epithelial permeability following acute smoking.¹²⁷ Thus, cigarette smoke has a detrimental effect on alveolar epithelial cell function that is, in part, oxidant mediated.

A major site of free radical attack is on polyunsaturated fatty acids in cell membranes producing lipid peroxidation, a process that may continue as a chain reaction to generate hydroperoxides and long-lived aldehydes. Levels of products of lipid peroxidation in plasma and BAL are significantly increased in healthy smokers and in patients with acute exacerbations of COPD, compared with healthy nonsmokers.^{126,130}

Several studies demonstrate increased levels of oxidants in exhaled air or breath condensates in COPD patients.¹³¹⁻¹³⁴ Furthermore, there is evidence that oxidative stress can cause increased lipid peroxidation in lung tissue in COPD patients compared with smokers who have a similar smoking history but have not developed the disease, with the level of lipid peroxidation correlating with the degree of airflow limitation.¹³⁵

Free iron is a critical element in many oxidative processes. Macrophages from smokers have been shown to contain more iron than those from nonsmokers, and they release more iron, thus potentially increasing the oxidant burden in smokers.^{136,137}

The major antioxidants in respiratory tract lining fluid include mucin, reduced glutathione, uric acid, protein (largely albumin), and ascorbic acid.¹³⁸ There is limited information on respiratory epithelial antioxidant defenses in smokers, and even less on those in COPD patients. Studies have shown that glutathione is elevated in the BAL from chronic smokers.¹²⁶ Even so, glutathione may not be present in sufficient quantities to deal with the excessive oxidant burden during acute smoking because cigarette smoke exposure depletes glutathione in a dose- and time-dependent manner.¹³⁹

Other antioxidants such as vitamin C and E have shown variable changes in COPD patients. Reduced levels of

vitamin E are present in the BAL of smokers compared with nonsmokers.¹⁴⁰ By contrast, other studies found a marginal increase in vitamin C in the BAL of smokers, compared with nonsmokers.¹⁴¹ The apparent discrepancy may be due to different smoking histories in chronic smokers, particularly the time of the last cigarette in relation to the sampling of BAL.

There is an imbalance between oxidants and antioxidants in COPD resulting in oxidative stress, which underlies many of the pathogenic mechanisms in COPD.¹⁴² Numerous studies documented increased expression of markers of oxidative stress in the lungs of COPD patients, compared with smokers who have not developed COPD. *4-hydroxy-2-nonenal* (4HNE), a highly reactive lipid peroxidation end product, reacts quickly with extracellular proteins to form adducts.¹⁴³ 4HNE adducts are present in greater quantities in airway epithelial and endothelial cells in the lungs of COPD patients, compared with smokers with a similar smoking history who have not developed the disease.¹³⁵ 4HNE can act as a chemoattractant for neutrophils¹⁴² and is also involved in numerous cellular functions such as cell proliferation, growth inhibition,¹⁴⁴ T-cell apoptosis,¹⁴⁵ and activation of various signaling pathways.¹⁴⁶ 4HNE has also been shown to activate the synthesis of the antioxidant glutathione, by induction of the glutamate cysteine ligase gene as an antioxidant response to increased oxidative stress, and also of a variety of proinflammatory genes coding for IL-8, MCP-1, EGF, and MUC5AC.¹⁴⁵ The presence of increased oxidative stress in COPD lungs is confirmed by the finding of increased expression of 8-hydroxy-2 deoxyguanosine, formed by the reaction of hydroperoxides with the DNA base guanosine.¹⁴⁷

Many actions of oxidative stress can potentially play a role in the pathogenesis of COPD. These include the inactivation of anti-proteases (such as A1AT or secretory leuko-protease inhibitor)¹⁴⁸ or activation of metalloproteases by oxidants, resulting in a protease/antiprotease imbalance in the lungs.¹⁴⁹ Oxidants can directly damage components of the lung matrix (e.g., elastin and collagen) and also interfere with elastin synthesis and repair.¹⁴²

Oxidative stress also influences the molecular mechanisms involved in proinflammatory gene expression. Gene activation by transcription factors is dependent on a number of factors, among which is the remodeling of DNA dependent on the nuclear histone acetylation/deacetylation balance,¹⁵⁰ controlled by the activities of *histone acetyltransferases* (HATs) and *histone deacetylases* (HDACs). DNA in the resting cell is coiled around a nucleosome core of histone residues. This configuration suppresses the accessibility of transcription factors such as NF- κ B to their cognate DNA sequences. Acetylation of the lysine residues in the core histones results in uncoiling of the DNA, increasing the accessibility of transcription factors and RNA polymerase 2 and hence increased gene transcription. Deacetylation, under the influence of HDACs, results in rewinding of the DNA around the histone proteins, decreasing gene transcription. Macrophages from cigarette smokers show a decrease in histone deacetylase activity,¹⁵¹ as has also been shown in the lungs of smoke-exposed animals associated with nitrotyrosine, 4HNE, and aldehyde-modified HDAC proteins, resulting in their enhanced degradation in the proteasome system and thus decreased HDAC activity.¹⁵²

Studies of resected lung indicate that HDAC2 activity is reduced in lung tissue in COPD, associated with lower HDAC2 RNA levels and expression of HDAC2 protein as a result of modification of HDACs by oxidants.^{153,154} This decrease in HDAC increased with disease severity and was associated with an increase in histone-4 acetylation at the IL-8 promoter and increased in IL-8 mRNA expression. Thus, molecular mechanisms such as transcription factor activation and chromatin remodeling, as a result of increased oxidative stress, may be responsible for perpetuating inflammation in COPD.

The most compelling data in support of the causal role of oxidative stress in the pathogenesis of emphysema have been provided by studies outlining the role of the master antioxidant transcription factor *nuclear erythroid-related factor 2* (NRF2) in the disease. NRF2 controls the expression of more than 100 gene products, including several of the most important antioxidant enzymes. Human lungs and alveolar macrophages from COPD patients have decreased expression of NRF2 transcriptional activity.^{155,156} The protective role of NRF2 in emphysema is underscored by the increased susceptibility of NRF2 null mice to cigarette smoke.^{157,158} Furthermore, enhancement of NRF2 expression using a small molecule activator protected wild type mice against cigarette smoke-induced emphysema.¹⁵⁹

Oxidative stress is linked to cell death, including alveolar cell apoptosis in the setting of human and experimental emphysema.¹⁶⁰⁻¹⁶² Moreover, oxidative stress underlies several of the mechanisms thought to participate in aging, which may lower the threshold for lung injury to cigarette smoke.¹⁶³

APOPTOSIS AND EMPHYSEMA

ALVEOLAR CELL DEATH IN EMPHYSEMA

Studies have documented that lung cells undergo apoptosis in emphysematous lungs, predominantly involving endothelial cells in the alveolar walls, compared with normal smokers' lungs.^{36,160,161,164} Experimental emphysema in animals can be produced by decreased VEGF or VEGF signaling, and studies in human lungs demonstrated decreased expression of VEGF and VEGF-receptor 2 expression in association with emphysema.¹⁶⁰ The aggregate of these data led to the concept of an alveolar maintenance program that was required for structural preservation of the lungs. Cigarette smoke is thought to cause destruction of this maintenance program, thus causing emphysema.

Lung tissue is destroyed due to the mutual interaction of alveolar cell apoptosis, oxidative stress, and protease/antiprotease imbalance.¹⁶⁴ This concept is supported by observations that antioxidant treatment prevented both apoptosis and emphysema induced by down-regulation of VEGF.¹⁶⁵

Inflammation can be triggered and amplified by alveolar injury, including either enhanced alveolar cell apoptosis or defective apoptotic cell clearance.¹⁶⁶ Targeted alveolar cell apoptosis using a chimeric peptide containing a lung homing sequence linked to a proapoptotic peptide led to emphysematous enlargement of murine lungs, associated with alveolar cell apoptosis, oxidative stress, macrophage

influx, and increases in ceramide levels.¹⁶⁷ Moreover, viral infections (such as influenza virus) can synergize with cigarette smoke to cause experimental emphysematous tissue destruction involving alveolar cell death and secondary lung inflammation.¹⁶⁸

ROLE OF AGING IN THE PATHOGENESIS OF EMPHYSEMA

The evidence of shared features between pulmonary emphysema and lung aging has led to the hypothesis that both conditions share underlying mechanisms, including oxidative stress, inflammation, and apoptosis.^{169,170}

The cellular equivalent of aging is senescence, which is characterized by a nonproliferative state in which cells are metabolically active and apoptosis resistant. A number of molecular and cellular mechanisms are associated with cellular senescence, including accumulation of DNA damage,¹⁷¹ impairment of DNA repair,¹⁷² epigenetic modifications in nuclear DNA,¹⁷³ protein damage¹⁷⁴ from oxidative stress, and telomere attrition.¹⁷⁵ Central to "end replication senescence" is the erosion of telomeres, with the ensuing activation of DNA repair enzymes, and the cell cycle control kinase inhibitors p53, p21, and p16. These signaling processes converge on de-phosphorylated retinoblastoma protein, which potently inhibits cell cycle progression. Cellular senescence also takes place in vivo, particularly in conditions associated with aging. Several markers of cellular senescence are present in vivo, particularly *senescence-associated β -galactosidase* (SA- β -gal), and the increased expression of cyclin-kinase inhibitors p16 and p21.¹⁷⁶

Cigarette smoke extract leads to increased SA- β -gal expression in cultured type II cells¹⁷⁷ or lung fibroblasts,¹⁷⁸ which have also been shown in lung fibroblasts from emphysematous lungs.¹⁷⁹ Oxidative stress enhances telomere shortening.¹⁸⁰ Furthermore, alveolar epithelial and endothelial cells in emphysematous lungs also have increased expression of p21 associated with decreased telomere length.¹⁸¹ The decreased telomere length parallels similar findings in circulating peripheral blood leukocytes. An association has been shown between blood leukocyte telomere length and pack-years of smoking,¹⁸² and telomeres are shorter in blood leukocytes from COPD patients compared with control subjects.¹⁸³

Sirtuins are type III histone deacetylases that have a role in a number of processes including stress resistance, apoptosis, cell senescence, differentiation, and aging.¹⁸⁴ *Sirtuin-1* (SIRT1) is essential for maintaining silent chromatin via the deacetylation of chromatin.¹⁸⁵ Environmental stress, such as cigarette smoke exposure, decreases SIRT1 levels in both macrophages in vitro and in rat lungs in vivo, associated with increased expression of inflammatory cytokines.¹⁸⁶ SIRT1 has been shown to be decreased in lung cells from COPD patients, compared with smokers who have not developed the disease, as a result of post-translational oxidative modification.¹⁸⁷ This would accelerate the process of aging and also enhance inflammation.

No single mechanism can account for the complex pathology in COPD. It is likely that interactions transpire between different mechanisms. For example, there are probably interrelationships between protease/antiprotease, oxidative stress, and apoptosis as destructive processes in

emphysema. Better understanding of the relative importance of these different pathogenic mechanisms will come from proof-of-concept therapeutic intervention studies.

EPIDEMIOLOGY

SIZE OF THE PROBLEM

COPD is a global health problem and a leading cause of mortality throughout the world. COPD will increase as a result of increased aging, as well as more widespread smoking in developing countries.

COPD is also associated with significant economic burden. In the European Union, the total direct costs of respiratory disease are estimated to be about 6% of the total health care budget.¹⁹⁰ In the United States, the direct costs of COPD almost 10 years ago were estimated to be \$29.5 billion and the indirect costs \$20.4 billion.¹⁹¹ COPD exacerbations account for the greatest proportion of the total COPD burden on the health care system, especially hospitalization costs, which increase rapidly as COPD severity increases. Indirect costs are difficult to assess in COPD. However, particularly in developing countries, the impact of COPD on workplace and home productivity outweighs direct costs for disease management.

PREVALENCE AND INCIDENCE

COPD prevalence data vary significantly because of geographic variation, differences in survey methods, and diagnostic criteria.¹⁹² The widespread under-recognition and under-diagnosis of COPD¹⁹³ means that self-report surveys will underestimate the true prevalence of COPD. In studies using spirometry, prevalence depends on the diagnostic criterion. Using the diagnostic criteria for a clinical diagnosis suggested by the *Global Initiative for Obstructive Lung Diseases* (GOLD)¹⁹⁴ will lead to higher figures than using *lower limit of normal* (LLN) for the FEV₁/FVC ratio.¹⁹⁵ The *Burden of Obstructive Lung Diseases* (BOLD) program has generally combined the fixed FEV₁/FVC ratio of 0.70 in combination with an FEV₁ less than 80% of the percentage predicted as the diagnostic criteria for COPD. BOLD has carried out surveys in several parts of the world and has documented more severe disease than previously found, with COPD prevalence using this criterion varying from 6% in Hannover, Germany, to 19% in Cape Town, South Africa¹⁹⁶ (Fig. 43-4). In these studies, a substantial prevalence (3% to 11%) of COPD among never-smokers was also found.

A random-digit dialed telephone survey in the United States (Behavioral Risk Factor Surveillance System, United States, 2011) found that 6.3% of adults had been told by a physician that they had COPD. Of these, approximately three quarters had pulmonary function testing and half of them received at least one daily medication.¹⁹⁷ In a BOLD survey in Kentucky, the prevalence of COPD defined as FEV₁/FVC less than 0.70 was 19.6%.¹⁹⁸

Incidence data are even fewer. The notion that 10% to 15% of smokers develop COPD is not justified.¹⁹⁹ However, the number may have value regarding clinically relevant COPD. Newer long-term follow-up studies indicate that the life-time prevalence of COPD in continuing smokers is close

Figure 43-4 Prevalence of moderate (stage II) and severe/very severe (stage III+) COPD in selected geographic regions. F, female; M, male. to 50%.^{200,201} The incidence of COPD in populations more heavily exposed to biomass fuel or other non-tobacco-related exposures is not known.

NATURAL HISTORY

Our conception of the natural history of COPD was formed by Fletcher and coworkers³ in their seminal studies in the 1970s and is most often illustrated as shown in Figure 43-5.

This concept emphasizes an excess FEV₁ decline as the hallmark of COPD and numerous epidemiologic studies have subsequently examined FEV₁ and defined risk factors according to their effect on change in FEV₁.²⁰²⁻²⁰⁸ Although the concept of an excess decline is undoubtedly correct,²⁰⁹ the view of COPD being caused by an excess decline alone is too simple, as Fletcher and coworkers acknowledged. Prenatal factors and perinatal events affect both lung growth and subsequent risk of COPD, and more recent studies have underlined the effect of early life events on subsequent COPD risk.^{210,211} The natural history of COPD thus starts prenatally and stretches over the entire lifetime; important factors include those responsible for lung and airway development at birth, for lung growth and maximally attained

lung function, for the plateau of lung function in early adulthood, and for subsequent decline in lung function.

Most studies have used simple spirometry to evaluate the natural history of COPD. It is today unclear if different phenotypes of COPD show different patterns of natural history, and we may in fact be dealing with several natural histories rather than just one.²¹² In established COPD, the subsequent course is highly variable; it seems clear that, in a substantial proportion of patients, disease progression, as evaluated by FEV1 decline, stops.^{213,214}

MORTALITY AND MORBIDITY

COPD is one of the most important causes of death in most countries. The Global Burden of Disease Study projected that COPD, which ranked sixth as a cause of death in 1990, will become the third leading cause of death worldwide by 2020¹⁸⁸; a newer projection estimated COPD will be the fourth leading cause of death in 2030.¹⁸⁹ These data likely underestimate the true COPD mortality because under-recognition and underdiagnosis of COPD affect the accuracy of mortality data, with COPD being listed only as contributory cause of death or not listed at all on the death certificate.²¹⁵ At the same time, mortality in COPD is strongly influenced by the presence of comorbidities.

Morbidity measures traditionally include hospitalizations, physician visits, and use of medications. Although COPD databases for these outcome parameters are less readily available and usually less reliable than mortality databases, the limited data available indicate that morbidity due to COPD increases with age. Morbidity from COPD may be affected by other comorbid chronic conditions (e.g., cardiovascular disease, musculoskeletal impairment, diabetes mellitus) that are related to COPD and may have an impact on the patient's health status, as well as interfering with COPD management.

RISK FACTORS

Risk factors can be considered as “exposures” and “endogenous factors” as shown in Figure 43-6 and discussed as follows.

GENETICS

A significant familial risk of airflow limitation has been observed in smoking siblings of patients with severe

COPD,²¹⁶ suggesting that genetic, together with environmental factors, could influence this susceptibility. Deficiency of A1AT, a major circulating inhibitor of serine proteases, is the best documented genetic risk factor for developing emphysema.^{217,218} Although A1AT deficiency is relevant to only a small part of the world's population, its potentiating effect on the harmful effects of smoking illustrates the interaction between genes and environmental exposures leading to COPD. Other single genes have some effect on the risk of developing COPD, including the alpha-nicotinic acetylcholine receptor, as well as the hedgehog-interacting protein gene, the *FAM13* gene, and the gene encoding MMP12. A few other genes have been implicated, but there remains a discrepancy between findings from analyses of COPD and lung function, as well as between *genome-wide association study* (GWAS) analyses and candidate gene analyses.²¹⁹⁻²²¹ In addition, none of the genes yet identified by GWAS in patients with COPD overlap with genes found to have an effect on the level of lung function.^{222,223}

SMOKING

Globally, cigarette smoking is the most commonly encountered risk factor for COPD. Smoking during pregnancy poses a risk for the fetus, by affecting lung growth and development in utero.^{224,225} Smoking in childhood and adolescence leads to stunting of lung growth and earlier decline in lung function than in nonsmokers.²²⁶ Adult cigarette smokers have a higher prevalence of respiratory symptoms, lower lung function, a greater annual rate of decline in FEV₁, a greater loss of lung density, and a greater COPD mortality rate than nonsmokers.^{202,227} The crucial factor seems to be the amount smoked and the extent of inhalation.²⁰⁴ Filtered cigarettes do not differ significantly from cigarettes without filters, and other types of tobacco and marijuana are also risk factors for COPD.^{228,229} Smoking cessation has, in several surveys, been shown to be associated with both a lower prevalence of respiratory symptoms and a slower decline in FEV₁, in both population studies and patient cohorts.^{204,213,230,231}

OTHER ENVIRONMENTAL FACTORS

Exposures other than smoking are risk factors for the development of COPD; however, less is known about the impact of single risk factors, their dose-response relationship, and the pathophysiologic, as well as clinical, features of nonsmoking-related COPD. Occupational exposures are a recognized risk factor for COPD.^{205,208,232} Data from the NHANES III survey found that the fraction of COPD attributable to occupational exposures was 19% overall and 31% among never-smokers.²³³ These figures are consistent with an American Thoracic Society statement that concluded that occupational exposures account for 10% to 20% of either symptoms or functional impairment consistent with COPD.²³⁴

Biomass fuel exposure is the term covering exposure to smoke from wood, animal dung, crop residues, and coal, typically burned in open fires or primitive stoves. Biomass fuel exposure is an important source of indoor air pollution in undeveloped countries, where almost 3 billion people are

Figure 43-6 COPD risk factors showing environmental exposures that interact with individual propensities.

exposed, and there is increasing evidence that this exposure is an important risk factor for COPD.²³⁵⁻²³⁹

INFECTIONS AND EXACERBATIONS

A history of severe childhood respiratory infection has been associated with reduced lung function and increased respiratory symptoms in adulthood.^{240,241} In established COPD, more focus has recently been on infections and exacerbations and the progression of disease. Susceptibility to infections plays a role in exacerbations of COPD, and exacerbations increase the excess decline in FEV₁,²⁴²⁻²⁴⁴ although the actual impact may be modest.²¹³

Tuberculosis has been shown to be a risk factor for COPD,^{245,246} but whether this is mainly due to airflow limitation from scarring or to true COPD is not clear.

ASTHMA AND BRONCHIAL HYPERREACTIVITY

Asthma and COPD are generally viewed as two different diseases with a variable overlap.²⁴⁷⁻²⁴⁹ However, asthma may also be viewed as a risk factor for the development of COPD. In the Tucson study, adults with asthma were found to have a 12-fold higher risk of acquiring COPD over time than those without asthma, after adjusting for smoking.²⁵⁰ A Dutch study of people with asthma found that 20% of subjects developed irreversible airflow limitation²⁵¹ and, in a Danish longitudinal population study, self-reported asthma was associated with an excess loss of FEV₁.²⁵²

In the European Community Respiratory Health Survey, bronchial hyperresponsiveness was second only to cigarette smoking as the leading risk factor for COPD, responsible for 15% of the population attributable risk.²⁵³ This is in accordance with previous studies showing a strong impact of bronchial hyperresponsiveness on FEV₁ decline, also in the absence of asthma.²⁵⁴⁻²⁵⁶

OTHERS

In the seminal study by Fletcher and coworkers,³ chronic bronchitis was not associated with decline in lung function. However, a more recent population study found an association between mucus hypersecretion and FEV₁ decline⁹ and, in younger adults who smoke, the presence of chronic bronchitis is associated with an increased likelihood of developing COPD.^{257,258} Most likely, chronic bronchitis affects FEV₁ decline by increasing lower respiratory tract infections.

COPD IN THE FUTURE

COPD used to be a disease of the smoking man in the industrialized world. Today, women have as much COPD as men, and although the prevalence seems to be stable or even increasing in many developed countries, this is more likely to be the result of ageing rather than increased risk.²⁵⁹ However, in developing countries, the exposure to biomass fuel with the added exposure to tobacco is bound to result in an increase in COPD morbidity and mortality and this will drive the real increase in COPD in the future.^{188,189} Thus, the typical COPD patient in 2030 is likely to live outside Europe and the United States and to have COPD based on mixed risk and with poorer access to treatment.

CLINICAL CHARACTERIZATION OF COPD

The clinical presentation of COPD is highly heterogeneous.²⁶⁰ The most common respiratory symptoms (breathlessness, cough, and expectoration), pathologic changes (chronic bronchitis, emphysema), and lung function abnormalities (mostly airflow limitation) vary greatly between patients and are poorly related (Fig. 43-7). Likewise, the relationship between many of the extrapulmonary manifestations and comorbid diseases frequently present in COPD are, by and large, independent of the severity of airflow limitation and also highly variable between patients.²⁶¹ Therefore, the clinical characterization of COPD should be multidimensional and should consider carefully several aspects and concepts, as discussed later.

SEVERITY, ACTIVITY, AND IMPACT OF COPD

The *severity* of a given disease (including COPD) relates to the “*extent of functional impairment of the target organ(s)*.”²⁶² Traditionally, the severity of COPD has been assessed by the severity of airflow limitation (FEV₁).¹ However, other domains of the disease (such as symptoms and frequency of exacerbations) are also clinically relevant and have been recently proposed by the *Global Initiative for Chronic Obstructive Lung Disease* (GOLD) to be considered in the clinical assessment of these patients.¹⁹⁴ To this end, several prognostic composite indices have also been proposed, including the BODE²⁶³ (Body mass index, airflow Obstruction, Dyspnea, and Exercise capacity) and the ADO (Age, Dyspnea, and airflow Obstruction)²⁶⁴ indices.

The *activity* of a disease relates to the “*level of activation of the biological processes that drive disease progression*.”²⁶² At variance with other chronic diseases, such as rheumatoid arthritis, this has been a largely forgotten concept in COPD. Traditionally, disease progression in COPD has been assessed by the decline in lung function with time^{203,204}. Recent research, however, challenged the paradigm that COPD was inevitably associated with an accelerated decline of FEV₁ with time by showing that lung function can be stable, or even improve over time in a proportion of treated COPD patients.^{213,214,265} Furthermore, because COPD is a highly heterogeneous disease,²⁶⁰ it is likely that different components of the disease (1) progress at different rates, (2) require different monitoring approaches to determine “progression” of clinical, functional, structural, and biologic variables, and (3) differ between patients depending on their specific clinical phenotype and/or the result of therapy.

How to determine COPD disease *activity* in the clinic has not yet been resolved, but several potential candidate markers of disease *progression* can be envisaged, including the following: (1) *clinical markers*, such as the presence/increase in symptoms,²⁶⁶ rate of FEV₁ decline,²¹³ frequency of exacerbations,²⁶⁷ unintended weight loss,²⁶⁸ poor exercise capacity, and/or appearance/worsening of comorbidities²⁶¹; (2) *imaging markers*, such as the presence/progression of emphysema,²⁶⁹⁻²⁷¹ airway disease including the presence of bronchiectasis²⁷² and/or a number of molecular imaging markers of inflammation²⁷³; and, finally, (3) *biomarkers of*

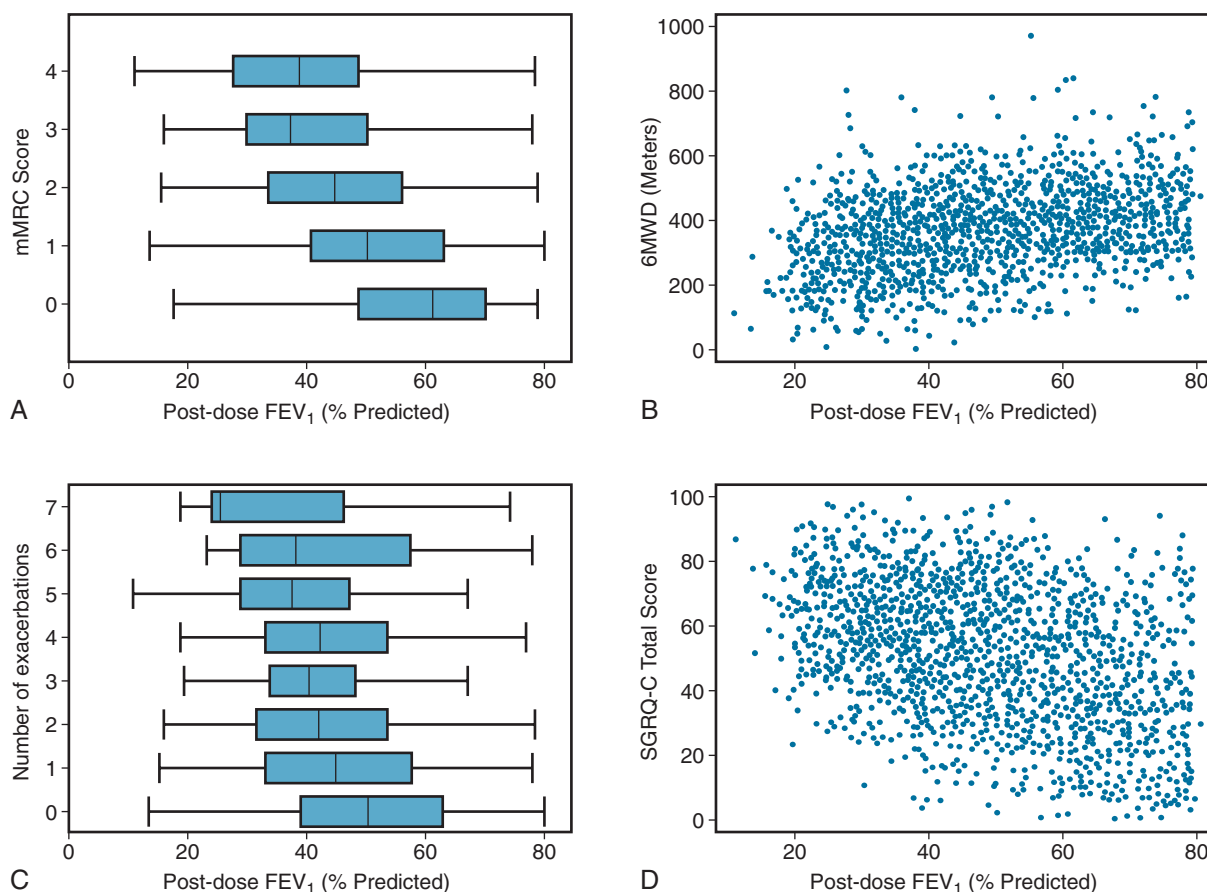

Figure 43-7 The severity of airflow limitation (FEV_1) is poorly related to **A**, level of breathlessness, as assessed by the mMRC questionnaire; **B**, exercise capacity as assessed by the six minute walk distance (6MWD); **C**, previous history of exacerbations; and **D**, health status as assessed by the Saint George Respiratory Questionnaire (SGRQ-C). For further explanations see text. (From Agustí A, Calverley P, Celli B, et al: Characterisation of COPD heterogeneity in the ECLIPSE cohort. *Respir Res* 11:122–136, 2010.)

inflammation/repair in circulating blood,^{274–276} exhaled air,²⁷⁷ and/or urine.²⁷⁸

The interaction between disease activity and severity is likely to be a key determinant of the *impact* of the disease on the patient, which is how this is perceived by the patient and how the disease interferes with his or her activities of daily living.²⁶² This has potentially relevant clinical implications because it is likely that disease severity and disease activity require different therapeutic approaches in order to minimize disease impact. Hence, although the treatment of disease severity should aim at improving the functional capacity of the patient (bronchodilators, oxygen therapy, rehabilitation, among others),¹⁹⁴ that of disease activity should aim at stopping or reducing the intensity of the biologic processes that drive disease progression (e.g., inflammation) using anti-inflammatory or proresolution therapeutic alternatives.²⁷⁹

EARLY VERSUS LATE DISEASE

Since the seminal paper of Fletcher and Peto,³ COPD has been considered as a progressive disease in which so-called “susceptible smokers” develop an accelerated decline in lung function (FEV_1) with age. However, because almost all studies published so far included patients with a mean age of 60 to 65 years, there is a paucity of information on

“earlier” stages of the disease. The term *early disease* refers then to an “early” time point in the natural history of the disease, at which the patient is diagnosed or studied (i.e., the age of the patient at that time point).²⁶² Yet often the concept of “early” disease is confused with that of “mild” disease, something that has to do with the severity of the disease (FEV_1) and not with its timing (age); clearly, an “old” patient with “mild” disease does not have “early” disease.²⁸⁰ Although the relationship between disease activity and disease severity is unclear, different possibilities can be conceived. For instance, in “early” disease (i.e., at young age), “disease activity” is likely to be high and severity low, whereas, depending on the natural history of the disease and/or the effectiveness of available therapies, in severe disease (at any given age) “disease activity” may be high, low, or intermediate.

COPD PHENOTYPES

Given the heterogeneous clinical presentation of COPD (see Fig. 43-7) there is considerable interest in identifying groups of patients with similar prognosis or therapeutic requirements.²⁸¹ Strictly speaking, a phenotype is defined by the observable properties (or *phenotypic traits*) of an organism, as determined by its genotype and modulated by its environment.²⁸² In order to provide some clinical perspective, a

recent consensus definition has proposed the concept of a *clinical phenotype*, which is defined as: “a single or combination of disease attributes that describe differences between individuals with COPD as they relate to clinically meaningful outcomes (symptoms, exacerbations, response to therapy, rate of disease progression, or death).”²⁸¹

Many disease characteristics (i.e., phenotypic traits) have been proposed as potential COPD *phenotypes*, but only a few have been validated prospectively according to this definition²⁸¹: (1) *alpha₁-antitrypsin deficiency*, where the specific gene/protein has been identified and specific therapy has been developed,²⁸³ (2) *upper lobe emphysema, with poor exercise tolerance after rehabilitation*, in patients with severe airflow limitation, whose survival improves with lung volume reduction surgery,²⁸⁴ and (3) *frequent exacerbations* (two or more per year²⁶⁷) that can benefit from anti-inflammatory therapy.^{244,285}

The identification and validation of novel clinical phenotypes can advance the clinical management of COPD by identifying novel therapeutic targets and determining the efficacy of a pharmacologic treatment/procedure in subgroups with specific attributes.²⁸⁶ To this end, well-designed, long-term longitudinal studies are necessary. The ECLIPSE, COPDgene, and SPIROMICS studies are beginning to address this need. Important caveats to consider include (1) certain disease attributes, such as dyspnea, depression, or exacerbations, could be viewed as phenotypic traits or outcomes, depending on the clinical context in which they are used²⁸¹; (2) the clinical presentation of some clinical phenotypes may change (for better or worse) over time due to either the effect of therapy and/or the natural course of the disease; (3) two prevalent diseases can coexist (for instance, COPD and asthma²⁴⁹ or COPD and obstructive sleep apnea²⁸⁷); (4) any given patient can belong to more than one clinical phenotype; (5) chronic respiratory failure, whose prognosis is improved by long-term home oxygen therapy in COPD^{288,289}, should not be considered a COPD phenotype because it is a final functional state common to many other diseases. It is, however, a marker of “severity” of the disease; and (6) it is plausible that the severity/activity of the disease should be assessed differently in different clinical phenotypes, and that the relationship between disease activity and disease severity might differ across phenotypes.

Potential clinical COPD phenotypes that require validation include (1) disproportionate dyspnea (it predicts excessive mortality,^{290,291} but the role of concomitant comorbidities is unclear.²⁹² Likewise, whether comorbidities constitute a specific phenotype or simply represent the coincidence of prevalent aging-associated diseases in the same patient is unclear^{261,292}); (2) persistent systemic inflammation, which is associated with increased mortality and exacerbation rate²⁷⁴; (3) chronic bronchitis, although available scientific evidence is controversial^{9,293}; (4) presence of chronic airway bacterial colonization^{294,295}; (5) emphysema²⁷¹ and its relation with pulmonary hyperinflation²⁹⁶ and lung cancer²⁹⁷; (6) the mixed phenotype asthma/COPD²⁴⁹; and (7) “out-of-proportion” pulmonary hypertension.²⁹⁸

GOLD COMBINED ASSESSMENT PROPOSAL

GOLD has recently proposed a new multidimensional system for the assessment and management of COPD

Figure 43-8 GOLD classification system. COPD patient groups according to the 2011 GOLD assessment proposal. * or 1 hospitalization. (Modified from Agusti A, Hurd S, Jones P, et al: Frequently asked questions (FAQs) about the GOLD 2011 assessment proposal of COPD. *Eur Respir J* 42:1391–1401, 2013).

patients that combines (1) the symptoms perceived by the patient, (2) the severity of the airflow limitation, and (3) the previous history of exacerbations.¹⁹⁴ In this proposed assessment, COPD patients are classified into four categories or groups (A, B, C, and D) (Fig. 43-8) that, together with the assessment of potential comorbidities, can assist clinicians in guiding therapy. There are still many unresolved questions about this new proposal, but there is no doubt that it is an important step toward a more personalized assessment and treatment of patients with COPD.²⁹⁹ It is possible that, in the future, the characterization and assessment of COPD will require the consideration of other domains not currently included in this proposal. Recently a “COPD control panel” that combines a “severity” module, an “activity,” module, and an “impact” module (Fig. 43-9) has been proposed as a potential way forward.³⁰⁰

The emerging fields of *systems biology* and *network medicine*³⁰¹ can help in understanding the complexity of the inter-related biologic mechanisms (so-called “intermediate phenotypes”^{302,303} or “endotypes”³⁰⁴) underlying different clinical phenotypes in COPD, as well as in the identification of clinically useful biomarkers³⁰⁵ and novel therapeutic targets.²⁹⁹ A more global, unbiased approach to “airway diseases” may eventually generate a new taxonomy with specific therapeutic implications.³⁰⁶

Key Points

- Pathology of COPD is heterogeneous with pathologic changes in the large airways (chronic bronchitis), small airways (bronchiolitis), and lung parenchyma (emphysema) that vary in their expression among patients.
- The pathogenesis of COPD is generally thought to result from an abnormal inflammatory response in the lungs to toxic particles and gases.
- No single mechanism can account for the complex pathology in COPD. It is likely that interactions among different mechanisms are involved, including inflammatory immune responses, protease/antiprotease and

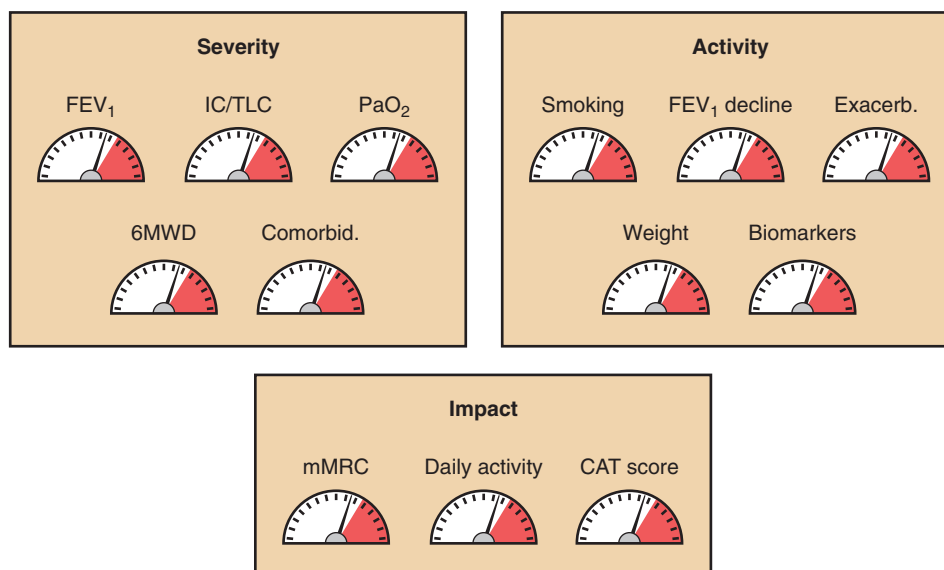

Figure 43-9 A COPD control panel. Collecting information in the three domains of severity, activity, and impact may provide guidance for optimal management of individual patients with COPD. 6MWD, 6-minute walk distance; CAT, COPD assessment test; FEV₁, forced expiratory volume in 1 second; IC/TLC, inspiratory-to-total lung capacity ratio; mMRC, modified Medical Research Council dyspnea scale; PaO₂, arterial oxygen pressure. (From Agusti A, MacNee W: The COPD control panel: towards personalized medicine in COPD. *Thorax* 68:687–690, 2013.)

oxidant/antioxidant imbalance, apoptosis, cell senescence, and aging.

- COPD often results from a combination of genetic susceptibility, poor lung growth, and an excess loss of lung function in adulthood.
- The clinical presentation of COPD is highly heterogeneous, and therefore the clinical characterization of COPD should be multidimensional and should consider factors related to disease severity, activity, and impact. Several disease phenotypes of COPD that benefit from specific treatment have been identified.

INTRODUCTION AND HISTORY

Chronic obstructive pulmonary disease (COPD), as it is currently defined, is a spectrum of lung abnormalities characterized physiologically by persistent airflow obstruction. The histologic abnormalities seen most commonly are lung tissue destruction, or emphysema, and airway disease, recognized clinically as chronic bronchitis. From a historical perspective, emphysema was recognized first. Dating back to the 17th and 18th centuries, clinicians recognized what were termed abnormally “voluminous” lungs.¹ In 1789, Baillie published a series of illustrations demonstrating the classic pathologic features of emphysema. A bit later, chronic bronchitis was described, best documented by the clinician, pathologist, and inventor of the stethoscope, Laennec. In his 1821 “A Treatise on the Diseases of the Chest,” Laennec describes lungs that are hyperinflated and do not empty well.² But, upon pathologic inspection, he also noted the “bronchus of the trachea are often...filled with mucous fluid.” At that time, smoking was not common and Laennec attributed the principal causes of this disease to environmental and genetic factors. However, it is important to note that Laennec identified both of the characteristic features of COPD: emphysema and chronic bronchitis.

By the 1940s, master clinicians were becoming familiar with an entity characterized by dyspnea on exertion in patients with physical signs of emphysema along with chronic bronchitis and asthma.³ However, the ability to diagnose this entity reliably was not possible until the invention of spirometry. In 1846, John Hutchinson invented the spirometer, which was capable of measuring vital capacity, but 100 years later, it was Tiffeneau who introduced the concept of a timed vital capacity as a measure of airflow that allowed the spirometer to become a diagnostic instrument for airflow obstruction.⁴ By the 1950s, clinicians recognized that specific spirometric and flow volume patterns indicated the presence of emphysema.⁵ In fact, the first edition of Hinshaw and Garland in 1956 depicted spiograms indicating airflow obstruction in emphysema.⁶

Groundwork for the modern definition of COPD was established at two major scientific conferences, the CIBA Guest Symposium⁷ in 1959 and the *American Thoracic Society* (ATS) Committee on Diagnostic Standards⁸ in 1962. The ATS committee defined chronic bronchitis clinically as chronic cough lasting at least 3 months for at least 2 years; emphysema was defined histologically as enlarged alveolar spaces; asthma was defined as airway hyperresponsiveness.⁹ It was then that Dr. William Briscoe at the ninth Aspen Emphysema Conference in 1965 first introduced the term “COPD.” Several years later, Drs. Charles Fletcher and Richard Peto provided support for the link between smoking and the development of COPD in their 1976 landmark book documenting that continued smoking accelerates the disease, whereas smoking cessation attenuates lung function loss.¹⁰

The modern definition of COPD, as put forth by the ATS and *European Respiratory Society* (ERS), describes it as “a preventable and treatable disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and is associated with an abnormal inflammatory response of the lungs to noxious particles or gases, primarily caused by cigarette smoking. Although COPD affects the lungs, it also produces significant systemic consequences.”⁹ While this definition describes a physiologic abnormality associated with exposure to noxious stimuli, the challenge that remains for both clinician and researcher is understanding the significant heterogeneity in disease presentation and progression that still exists within this umbrella definition.

CLINICAL FEATURES

SYMPTOMS

Individuals with early COPD are often asymptomatic. However, as the disease progresses, dyspnea, wheezing, cough and sputum production typically become more

Figure 44-1 Dynamic hyperinflation. Volume tracing from a patient with severe COPD who demonstrated ventilatory dependent dynamic hyperinflation. Inspiratory capacity (IC) decreases and end-expiratory lung volume (EELV) increases as ventilation increases during exercise. IRV, inspiratory reserve volume; TLC, total lung capacity; VT, tidal volume. (From Dolmage TE, Evans RA, Goldstein RS: Defining hyperinflation as ‘dynamic’: moving toward the slope. *Respir Med*. Mar 7, 2013. Figure 1.)

prominent. Any of these features should trigger an evaluation including spirometry both for diagnosis, if not already established, and for disease staging. Early in the disease course, dyspnea may be experienced only with exertion and patients may attribute these symptoms to other factors and not seek treatment. Patients may also modify their activities to avoid dyspnea so that the progression of pulmonary limitation may be rather insidious. In fact, patients’ activity may be severely limited even when they believe their disease process is still mild.¹¹ Eventually, however, as the disease progresses, dyspnea may ultimately be present with activities of daily living. Whereas the mechanism for dyspnea in COPD is likely multifactorial, exercise-induced air trapping otherwise known as “dynamic hyperinflation” likely plays a significant role (Fig. 44-1).

As with dyspnea, patients may attribute cough to other factors such as smoking and therefore may not complain about this symptom unless prompted. In general, current smokers have more sputum production, which paradoxically may increase transiently after smoking cessation.¹² While the presence of cough and sputum production in COPD is often more variable than the presence of dyspnea, it can significantly impact quality of life.¹¹ Sputum, when present, tends to be mucoid, clear to white in appearance, and more purulent with exacerbations. Chronic bronchitis is also clinically significant because it is associated with more frequent exacerbations¹³ and has specific therapeutic implications (see [Treatment](#)).^{14,15} Excessive sputum production (more than 2 to 3 tablespoons daily) may indicate the presence of bronchiectasis, which has been reported to range in prevalence between 29% and 52% in moderate-to-severe COPD and has been associated with increased mortality.¹⁶ Hemoptysis may be seen with both chronic bronchitis and bronchiectasis, particularly during COPD exacerbations. However, the presence of hemoptysis in a patient with COPD should raise concern for other possible causes, including lung cancer, given the increased risk for lung cancer in this patient population.¹⁷

Several instruments have been developed to assess health status in COPD, most notably the *St. George’s Respiratory Questionnaire*¹⁸ (SGRQ) and the *COPD Assessment Test*¹⁹

(CAT) (Fig. 44-2). Both are multidimensional instruments encompassing symptoms such as cough and sputum production as well as breathlessness and activity limitation. Both the SGRQ and CAT demonstrate rough but imperfect correlations with *forced expiratory volume in 1 second* (FEV_1) but, more importantly, demonstrate changes after interventions^{20,21} and with exacerbations.^{22,23} While the SGRQ is longer and used primarily in the research setting, the CAT consists of only eight questions and is practical for use within the clinical setting. The Modified Medical Research Council scale is a 5-point dyspnea scale²⁴ that, while not developed specifically for COPD, is relevant because it relates to mortality in COPD alone²⁵ or when used to calculate the BODE (BMI, obstruction, dyspnea, exercise capacity) index, a mortality predictor in COPD²⁶ (Table 44-1).

PHYSICAL EXAMINATION

Early in the course of the disease, no specific abnormalities may be noted on physical examination. Wheezing may or may not be present and does not necessarily relate to the severity of airflow obstruction. Prolonged expiratory time is a more consistent finding in COPD, particularly as the disease progresses. A forced expiratory time of more than 6 seconds corresponds to an FEV_1 /forced vital capacity (FVC) ratio of less than 50% to 60%.^{27,28} In very severe disease, patients develop physical signs indicative of hyperinflation, including a barrel-shaped chest, decreased breath sounds, distant heart sounds, and increased resonance to percussion. Patients may breathe in a “tripod” position in which the individual leans forward and supports his or her upper body with extended arms. This maneuver takes advantage of the accessory muscles of the neck and upper chest to increase air movement. Patients with severe disease may also use pursed-lip breathing, which involves exhaling through tightly pressed, pursed lips. This technique creates back-pressure and is thought to reduce dynamic hyperinflation although it may also work by reducing bronchoconstriction via neutrally mediated mechanisms.²⁹

In patients with severe disease, other systemic manifestations may include signs of cor pulmonale, or right-sided

How is your COPD?

For each item below, place a mark (✓) in the box that best describes your experience.

Example: I am very happy

Four variables identified as being predictive of survival in patients with COPD, and the values (0–3) assigned to each variable by category. FEV₁, forced expiratory volume in 1 s; MMRC, modified Medical Research Council.

*Values for body mass index are 0 or 1 owing to the inflection point in the inverse relationship between survival and body mass index at a value of 21 kg/m².

[†]FEV₁ categories are based upon stages identified by the American Thoracic Society.

(From Celli B, Goldstein R, Jardim J, Knobil K: Future perspectives in COPD. *Respir Med* 99:S41–S48, 2005, Table 1.)

hyperventilation and often manifest muscle wasting and weight loss. Compared with blue bloaters, pink puffers are less hypoxemic and therefore appear “pink.” Blue bloaters typically have chronic bronchitis and tend to have decreased ventilation and greater *ventilation-perfusion* (V/Q) mismatch than pink puffers, leading to hypoxemia and hence cyanosis and to cor pulmonale with edema or “bloating.”

PULMONARY FUNCTION TESTING AND DIAGNOSIS

Spirometry

Pulmonary function testing (see Chapter 25) and, in particular, spirometry is essential to establish a diagnosis of COPD. While symptoms suggest a diagnosis, unfortunately their predictive value for a diagnosis of COPD is poor.³⁰ Several screening tools have been developed, including questionnaires³¹ and questionnaires used in conjunction with peak expiratory flow.³² Several studies suggest that among the various risk factors, older age and smoking history are the two most important risk factors for development of COPD.^{30,31,33} Spirometry can be performed in the physician’s office and should be done in any patient with symptoms (e.g., cough, sputum, dyspnea) and risk factors. When performing spirometry, a subject exhales forcefully and the FEV₁ is compared against the total air exhaled, which is the FVC. COPD is defined by a reduction in the FEV₁/FVC ratio. The degree of FEV₁ reduction defines the severity of airflow obstruction. The flow volume loop in COPD typically has a concave appearance and the volume-time curve demonstrates a prolonged expiratory time (Fig. 44-3).

The ATS and the *Global Initiative for Chronic Obstructive Lung Disease* (GOLD) recommend that post-bronchodilator values be used to help distinguish COPD from asthma. GOLD recommends an FEV₁/FVC less than 0.70 as the threshold for presence of airflow obstruction.³⁴ Rather than using the fixed ratio, the ATS/ERS recommends using the fifth percentile for the lower limit of normal.⁹ In general, the fixed ratio approach leads to overdiagnosis in older subjects

Figure 44-3 Flow volume loop in COPD. **A**, The tracing shows a concave flow volume loop with reduction of flow at all lung volumes. The dots indicate the expected flow at various lung volumes. **B**, The volume-time curve shows a prolonged expiratory time. The dot demonstrates the predicted FEV₁.

Table 44-2 GOLD Classification of Severity of Airflow Limitation in COPD, Based on Post-Bronchodilator FEV₁

In Patients with FEV ₁ /FVC < 0.70	
GOLD 1: mild	FEV ₁ ≥ 80% predicted
GOLD 2: moderate	50% ≤ FEV ₁ < 80% predicted
GOLD 3: severe	30% ≤ FEV ₁ < 50% predicted
GOLD 4: very severe	FEV ₁ < 30% predicted

COPD, chronic obstructive pulmonary disease; FEV₁, forced expiratory volume in 1 second.

Global Strategy for the Diagnosis, Management and Prevention of COPD, Global Initiative for Chronic Obstructive Lung Disease (GOLD) 2014. Available from: <http://www.goldcopd.org/>.

because the FEV₁/FVC ratio declines with age, even in healthy individuals.³⁵ However, the fixed ratio approach carries the advantage of simplicity.

While COPD severity has typically been graded based on FEV₁% predicted, which is part of the GOLD (Table 44-2) and ATS/ERS recommendations, recent updates to the GOLD recommendations now incorporate symptoms and exacerbation risk as part of disease staging.

Lung Volumes

Other lung volumes including *total lung capacity* (TLC) and *residual volume* (RV) must be measured via plethysmography, which is typically performed in a pulmonary function laboratory. TLC is increased in COPD, particularly in the

presence of emphysema where there is significant loss of elastic recoil, resulting in lung hyperinflation. Increases in RV and functional residual capacity may also be seen. RV tends to increase to a greater extent than TLC, leading to an increase in the RV/TLC ratio. Vital capacity in COPD is also typically decreased because of hyperinflation.

Diffusing Capacity

Diffusing capacity for carbon monoxide (DL_{CO}) reflects the alveolar capillary blood volume and consequently is decreased in the presence of emphysema, but may also be reduced in the presence of other abnormalities that affect the alveolar capillary bed including pulmonary fibrosis. Near-normal spirometry and lung volumes in the setting of severely reduced diffusing capacity and radiographic evidence of emphysema should suggest a possible diagnosis of combined pulmonary fibrosis emphysema syndrome.³⁶

Exercise Testing

The *6-minute walk test* (6MWT) is probably the most frequently employed exercise test in COPD. The distance that a patient can walk in 6 minutes is termed the *6-minute walk distance* (6MWD).³⁷ Measuring distance walked during a defined time period was first described in the early 1960s.³⁸ An advantage of the 6MWT is that it requires little training to administer and no specialized equipment. While a 6MWT is not required to make a diagnosis of COPD, it allows the clinician to assess oxygenation during ambulation and the potential need for supplemental oxygen. 6MWD is also frequently employed during lung transplant evaluation to gauge functional status and prognosis. 6MWD has been demonstrated to relate to mortality in COPD and is a component of the BODE mortality index.²⁶ The 6MWT however does not provide diagnostic information regarding specific causes for dyspnea or exercise limitation, which can only be obtained through more formal *cardiopulmonary exercise testing* (CPET). CPET can be performed with either a treadmill or cycle ergometer.³⁹ A large number of parameters can be measured or derived during a CPET, including *maximal oxygen uptake* ($\dot{V}O_2$), *carbon dioxide output* ($\dot{V}CO_2$), maximal work rate, and anaerobic threshold. While there is good correlation between 6MWD and peak oxygen uptake in end-stage lung disease,^{40,41} the 6MWT should be considered complementary to the CPET. Most patients do not achieve maximal exercise capacity during the 6MWT and consequently the 6MWD may better reflect functional exercise capacity.⁴² The 6MWD also correlates better with quality of life measures; therapeutic interventions resulting in changes in 6MWD also correlate with improvements in dyspnea.⁴³⁻⁴⁵ Some form of exercise testing is typically employed before and after pulmonary rehabilitation to assess improvement. CPET is also a necessary part of evaluation for *lung volume reduction surgery* (LVRS), because LVRS may provide a survival benefit for those with a low work rate after pulmonary rehabilitation.⁴⁶

IMAGING

Chest radiography and *computed tomography* (CT) are the two imaging modalities most commonly used in COPD. While not required to diagnose COPD, imaging can be helpful to rule out concomitant processes. Chest radio-

graphs are frequently obtained to investigate dyspnea or hemoptysis or to look for pneumonia, heart failure, lung cancer, or pneumothorax. Chest radiography is not particularly sensitive or specific for the diagnosis of COPD. There are certain features, however, that are often seen in COPD. Radiolucency, diaphragmatic flattening, and increased retrosternal airspace on the lateral radiograph may be seen when hyperinflation is present (Fig. 44-4, Video 44-1). Occasionally large bullae may manifest as radiolucent areas.

Chest CT allows better detection and quantification of emphysema than does traditional chest radiography. Areas of low attenuation are a marker of emphysema; thickened airways indicative of bronchial thickening may also be seen (Fig. 44-5). If expiratory views are obtained, areas of air trapping indicative of small airway obstruction and emphysema may also be seen. CT is not indicated in the routine diagnosis or evaluation of COPD, but can be helpful when evaluating individuals with very severe COPD. CT imaging is required to quantify emphysema extent and distribution for the purposes of LVRS.⁴⁶ Individuals with very severe COPD undergoing transplant evaluation typically require a chest CT to rule out the presence of lung cancer and aid with surgical planning. CT imaging is also helpful when the clinician is concerned about a concomitant process such as interstitial lung disease which may be suggested on pulmonary function testing (see section on PFT's) or when hemoptysis or other unexplained changes in symptoms develop. Bronchiectasis, which may be reflected by copious sputum production and cough and has been associated with increased mortality,¹⁶ is also best assessed on CT.

Although CT is not required for routine practice, the potential clinical importance of CT imaging is becoming better appreciated. Several studies demonstrate a strong relationship between emphysema and both lung function decline^{47,48} and mortality.^{49,50} Bronchial thickening as assessed by CT also appears to have a strong relationship with symptoms as measured by the SGRQ.

The COPD patient population is at increased risk for lung cancer and the mortality benefit of screening CTs in smokers has now been established.⁵¹ Therefore a low-dose screening CT for lung cancer in individuals aged 55 to 74 years with at least a 30 pack-year smoking history, including those who quit in the preceding 15 years, may be appropriate (see Chapters 18 and 53).

LABORATORY TESTING

Arterial Blood Gases

Arterial blood gases (ABGs) are not indicated as part of the routine evaluation for patients with mild to moderate COPD. For many patients, pulse oximetry will suffice to provide an estimate of oxygen saturation. However, ABGs can be helpful to assess hypoxemia and to provide information regarding hypercapnia, particularly in individuals with more severe disease or during an acute exacerbation. ABG abnormalities also tend to worsen during exercise⁵² and sleep.⁵³ Early in the disease course, mild to moderate hypoxemia without hypercapnia is typically seen. Later in the disease course, hypercapnia may develop, particularly in individuals with FEV_1 less than 1 L.

Figure 44-4 Centriacinar emphysema. Frontal (A) and lateral (B) chest radiograph in a 54-year-old female smoker with centriacinar emphysema. Note the very large lung volumes, with hyperlucency primarily seen in the upper lobes, consistent with a centriacinar emphysema pattern. Flattening of the diaphragms (arrows), a prominent retrosternal clear space on the lateral radiograph (double arrow), and a small-appearing heart on the frontal radiograph are findings consistent with abnormally increased lung volumes and are typical of advanced emphysema. The upper lobe lucency typical of centriacinar emphysema contrasts with the lower lobe predominant lucency seen in patients with panacinar emphysema. See [Video 44-1](#) for CT video of this patient. 

Erythrocytosis. Elevated hemoglobin may be seen in COPD, particularly in the presence of chronic hypoxemia. A hemoglobin value is also helpful in the evaluation of dyspnea because anemia is a common cause of dyspnea that should be ruled out. In addition, DL_{CO} is most accurate when adjusted for hemoglobin.

Serum Bicarbonate. An elevated serum bicarbonate can suggest chronic hypercapnia; in the setting of hypercapnia, serum bicarbonate is increased due to compensatory metabolic alkalosis.

Alpha₁-Antitrypsin Deficiency

The ATS guidelines recommend testing for A1AT deficiency for all individuals with persistent airflow obstruction.⁵⁴ A1AT is a protease that inactivates neutrophil elastase. Clinical features suggestive of A1AT deficiency include emphysema at a young age, emphysema in an individual with minimal or no smoking history, lower lobe predominant emphysema, and a family history of emphysema. However, A1AT deficiency can also be present in patients with more typical COPD presentations. In individuals with established COPD, diagnostic testing is recommended. Concern for the diagnosis is raised based on A1AT serum levels below 11 micromol/L (approximately 50 mg/dL using nephelometry (i.e., immunoturbidimetry) and 80 mg/dL by radial immunodiffusion) but should be confirmed with genotyping (high-risk genotypes include S, Z, and null alleles as the most deficient). Occasionally the serum level and genotyping are discordant; in this situation, protein phenotype analysis via electrophoresis can identify alleles with abnormal protein migration patterns. The chest radiograph and CT show the predominantly

lower lobe distribution of emphysema, consistent with a panacinar pattern (Fig. 44-6, [Video 44-2](#)) and different from the more common centriacinar pattern (see Fig. 44-4 and [Video 44-1](#)). 

Sputum. Sputum evaluation is not indicated in the routine diagnosis and care of the COPD patient. In patients with stable disease, sputum examination typically reveals a predominance of macrophages and few bacteria. During exacerbations, the number of organisms on Gram stain typically increases. The most common pathogens identified on sputum culture include *Haemophilus influenzae*, *Moraxella catarrhalis* and *Streptococcus pneumoniae*.⁵⁵ Less frequently identified organisms include *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and other gram-negative rods. However, the relationship between identification of organisms in sputum and pathogenic contribution to acute exacerbations has been questioned because longitudinal studies have suggested that the incidence of bacterial isolation from sputum during an acute exacerbation of COPD was no different from that of the stable state,^{56,57} although bacteria identified in sputum during stable COPD have been associated with a greater exacerbation frequency⁵⁸ and lung function decline.⁵⁹ In general, exacerbations typically respond to empirical treatment.

COMPLICATIONS

PNEUMOTHORAX

Pneumothoraces may develop spontaneously in patients with COPD. Depending on the degree of respiratory

Figure 44-5 Two radiologic phenotypes of COPD. CT of two patients with COPD demonstrating the significant difference in the type of disease that may be present. Two patients with moderately severe disease are shown. **A**, The patient demonstrates predominantly emphysema whereas the patient shown in **B** demonstrates predominantly airway thickening. (From Han MK, Kazerooni EA, Lynch DA, et al: Chronic obstructive pulmonary disease exacerbations in the COPDGen study: associated radiologic phenotypes. *Radiology* 261:274–282, 2011.)

impairment, a pneumothorax may result in significant dyspnea and even acute respiratory failure. Pneumothoraces are treated similarly in COPD as in other conditions, although patients with severe emphysema are at increased risk for persistent air leaks, which may be difficult to treat.

GIANT BULLAE

Emphysema may present with large bullae that can occupy a good portion of the hemithorax. Surgical treatment can be considered if compression of adjacent lung tissue is significant and surgical intervention is expected to improve pulmonary mechanics.⁶⁰ Bullae may also become infected. An increased frequency of lung cancer has been reported in association with large bullae, seen either as a mass within the bulla or a thickening of the wall.^{61,62}

PNEUMONIA

Pneumonia is not uncommon in patients with COPD and should be in the differential diagnosis for any patient with COPD presenting with increased dyspnea, cough, sputum production, and/or fever, which can make it difficult to distinguish from an acute exacerbation of COPD without a chest radiograph. While COPD is believed to increase the

Figure 44-6 Panacinar emphysema. Frontal chest radiograph in a 51-year-old woman with α_1 -protease inhibitor deficiency presenting for lung transplant evaluation. Note the very large lung volumes with hyperlucency primarily seen in the bases, consistent with panacinar emphysema, as well as flattening of the diaphragms. Contrast the lower lobe lucency in this radiograph with [Figure 44-4](#), which shows upper lobe hyperlucency in a patient with centriacinar emphysema. See [CT Video 44-2](#) of this patient.

risk for pneumonia, epidemiologic data are limited.^{63,64} *Inhaled corticosteroids* (ICS), which are frequently employed in the treatment of COPD because they reduce the frequency of COPD exacerbations, have been associated with an increased risk for pneumonia, particularly in older patients with COPD⁶⁵. All patients with COPD should be immunized against pneumococcus.

COR PULMONALE

Cor pulmonale refers to altered structure or function of the right ventricle resulting from *pulmonary hypertension* (PH) associated with chronic lung disease (see Chapter 59). The prevalence of cor pulmonale in COPD is not known with certainty but reported prevalence ranges from 1% to more than 70% depending on the patient population examined and the methodology employed for defining PH.⁶⁶ When PH develops in the setting of COPD, the severity tends to be modest; severe resting PH due to COPD is relatively uncommon (see Fig. 59-3). Signs and symptoms of cor pulmonale include an increase in dyspnea, chest pain, and syncope. Severe cor pulmonale often presents with an increase in lower extremity edema, which should prompt further investigation. Other physical examination findings include right ventricular heave, prominent pulmonic component to the second heart sound, tricuspid regurgitation murmur, and a right-sided S4. Electrocardiographic findings may include right axis deviation, evidence of right ventricular hypertrophy, and right bundle-branch block (see Fig. 59-6), but overall these findings are rather insensitive for diagnosis of PH. Echocardiography can be diagnostically helpful (see

Fig. 59-7 and Videos 59-1AB and 59-2AB), although not infrequently images are limited in patients with parenchymal lung disease and hyperinflation. In addition, the correlation between echocardiogram and right heart catheterization is imperfect; sensitivity tends to be better than specificity, suggesting that normal results on echocardiogram can help exclude significant cor pulmonale. Right heart catheterization remains the “gold standard” for diagnosis (see Fig. 59-9). PH in COPD is associated with worse outcomes, including increased risk for hospitalization⁶⁷ and worse survival.^{68,69} There are few data to support the use of vasodilators for treatment of PH in COPD. Oxygen is the only therapy for PH in COPD and also improves mortality in appropriately selected patients.⁶⁶

SLEEP DISORDERS

As many as 40% of COPD patients report sleep difficulties such as poor sleep quality or difficulties initiating or maintaining sleep.⁷⁰ The combination of COPD and *obstructive sleep apnea* (OSA) is commonly referred to as “overlap syndrome.” The frequency of OSA in the COPD patient population has been estimated to be approximately 16%,⁷¹ which is roughly similar to that of the general population, although the consequences of OSA in patients with COPD are more significant. Compared to patients with OSA alone or with COPD alone, patients with COPD with OSA tend to have more severe nocturnal hypercapnia and hypoxemia as well as increased risk for PH.⁷² OSA in COPD is also associated with poorer quality of life, frequent exacerbations, and increased mortality.^{73,74} Diagnosis of OSA in COPD is important because continuous positive airway pressure therapy for patients with overlap syndrome has been associated with both decreased risk of death and decreased incidence of severe exacerbations.⁷⁴

SYSTEMIC MANIFESTATIONS AND COMORBIDITIES

Cardiovascular Disease

Ischemic cardiovascular disease is a leading cause of death in COPD.⁷⁵ Tobacco use is a shared risk factor that contributes to this association, but epidemiologic data suggest impaired lung function is an independent risk factor for increased cardiovascular mortality even when adjusted for smoking status.⁷⁶ Among those with COPD, FEV₁ also predicts the presence of atherosclerosis⁷⁷ and cardiovascular mortality.^{78,79} Patients with COPD are also at increased risk for hospitalization due to cardiovascular events.⁸⁰ Atherosclerosis is a disease of systemic inflammation,⁸¹ which may help explain the link to COPD. Elevated C-reactive protein levels correlate not only with the presence of COPD but also with the presence of exacerbations, severity of lung function, and risk for hospitalization and death.⁶⁶ Although clinicians need to be aware of the increased risk for the presence of both disorders, no therapeutic strategies have yet been demonstrated to benefit this subgroup of patients specifically. Cardioselective β -blocker medications that are frequently used in patients with cardiovascular disease have traditionally raised safety concerns in patients with COPD. However, while clinicians should be aware that β -blockers

can theoretically worsen bronchospasm, accumulating data from several studies now suggest that β -blocker medication in COPD actually reduces all-cause mortality, suggesting an overall benefit to the use of β -blockers in COPD.⁸²⁻⁸⁴

Osteoporosis

A clear association between osteoporosis and COPD has been established, with studies suggesting a twofold to fivefold increase in prevalence of osteoporosis in patients with COPD compared with age-matched controls.^{85,86} Multiple shared risk factors between COPD and osteoporosis likely influence this association, including oral and inhaled steroid use, smoking, and low body mass index. However these factors do not completely explain the association because lower bone mineral density in patients with COPD has been documented even in the absence of systemic steroids.⁸⁷ Clinicians must be mindful of this association in both their male and female patients with COPD. Pulmonary rehabilitation improves the functional status of patients with COPD and may diminish fracture risk by decreasing the risk of falls.⁸⁸

Diabetes

As with osteoporosis, diabetes is another comorbidity with increased prevalence in COPD. Decreased lung function has been associated with the coexistence of metabolic syndrome as well as the development of insulin resistance and diabetes.⁸⁹⁻⁹¹ The cause for this association is not known with certainty. ICS may be a contributing factor. Some data suggest a dose-dependent association between ICS use and diabetes control or new-onset diabetes,⁹² while a retrospective analysis of 8 COPD trials and 26 asthma trials found no association between ICS use and new onset diabetes or hyperglycemia.⁹³

Gastroesophageal Reflux Disease

The prevalence of gastroesophageal reflux disease in COPD also appears to be increased.^{94,95} More importantly, gastroesophageal reflux disease in the setting of COPD has specific clinical implications. Reflux in COPD is associated with poorer quality of life,⁹⁶ as well as more frequent exacerbations.^{95,97} Reflux may also be more common in COPD patients with chronic bronchitis⁹⁸. A clear cause for the association between gastroesophageal reflux disease and COPD has not been identified. Unfortunately, only limited data suggest that treatment for gastroesophageal reflux disease may reduce the risk of exacerbations.⁹⁹

Depression and Anxiety

Coexistent depression and anxiety are prevalent in COPD,^{100,101} with conservative estimates suggesting anxiety and depression may be present in at least 10% of the general COPD population. Significantly higher estimates have been reported for patients with severe COPD.¹⁰² Risk factors for depression in COPD also include limited mobility, need for supplemental oxygen therapy, comorbid conditions, and female gender.^{103,104} Patients with COPD and comorbid depression and anxiety experience poorer clinical outcomes. Patients with anxiety are at increased risk for COPD exacerbations and higher mortality.¹⁰⁵ Depressive symptoms are also associated with increased risk of

death.^{106,107} Specific therapies for anxiety and depression have not been demonstrated to improve COPD outcomes, although pulmonary rehabilitation has been shown to improve not only anxiety and depression but also other outcomes in patients with COPD, including quality of life and functional capacity.¹⁰⁸

DIFFERENTIAL DIAGNOSIS

Several disorders may mimic aspects of COPD, and certainly many conditions may be associated with dyspnea. However, there are a handful of disorders that are particularly challenging because they may be associated with cough, sputum production, airflow obstruction, or emphysema-like radiographic changes. Careful clinical assessment can help differentiate these disorders from COPD although, in some instances, these disorders may be present in addition to COPD.

CHRONIC OBSTRUCTIVE ASTHMA

Chronic asthma may be associated with the development of persistent airflow obstruction that is not completely reversible (i.e., due to “remodeling”). Hence, a clear distinction from COPD may not be possible; chronic asthma may also coexist with COPD. However, several clinical features tend to be more likely associated with each of the two disorders. In general, the age of onset for asthma tends to be earlier. Asthmatic patients may have a history of atopy and a family history of asthma. Airflow obstruction abnormalities are usually less severe with asthma, with greater prevalence of reversibility. Sputum production is less common in asthma. These patients also tend to have less of a smoking history and greater steroid responsiveness than patients with COPD. Chronic asthma is also not associated with emphysema; the DL_{CO} is normal or increased in chronic asthma, whereas it is decreased in emphysema.

CHRONIC BRONCHITIS WITHOUT AIRFLOW OBSTRUCTION

Chronic cough and sputum production may be present in the absence of airflow obstruction. The accepted definition for chronic bronchitis is a productive cough for 3 months for 2 successive years.¹⁰⁹ Diagnostically, this is often mistaken for COPD because chronic bronchitis even in the absence of airflow obstruction is often associated with smoking. Chronic exposure to poor air quality or industrial dusts/fumes also increase risk for this disorder. While no specific therapies have been developed for chronic bronchitis without airflow obstruction, the morbidity and mortality associated with this disorder should not be ignored. Such patients still experience poorer quality of life and increased risk of death as opposed to healthy controls.¹¹⁰⁻¹¹²

BRONCHIECTASIS

Bronchiectasis is characterized by dyspnea and in particular copious mucopurulent sputum that tends to be greater than in typical COPD. Diagnosis can be established with the aid of high-resolution CT wherein bronchial wall thicken-

ing and luminal dilation is seen. It is not uncommon to see concurrent mild bronchiectasis in both COPD and asthma. Bronchiectasis in COPD is associated with increased mortality.¹⁶ Moderate to severe bronchiectasis should raise a clinician's concern for immunodeficiency, cystic fibrosis, rheumatic disorders, ciliary motility disorders, α_1 -antitrypsin deficiency, allergic bronchopulmonary aspergillosis, and mycobacterial infection.

BRONCHIOLITIS OBLITERANS

Bronchiolitis obliterans (BO) is also known as constrictive bronchiolitis. This disorder is characterized by submucosal fibrosis resulting in narrowing of the bronchiolar lumen. BO is a known complication of lung, heart, and bone marrow transplants but also may be seen in association with connective tissue diseases and inflammatory bowel disease. Inhalation of dusts or toxins, infection, and drug reactions are less frequent causes of BO. In some cases, no clear etiology is identified. As opposed to those with COPD, patients with BO may have no significant smoking history and typically do not have significant emphysema on CT, which may show only hyperinflation and air trapping. Mosaic attenuation indicative of localized air trapping is common. Bronchial wall thickening may also be present. Pulmonary function testing demonstrates severe, progressive, and irreversible airflow obstruction but is not typically associated with severe DL_{CO} impairment. Unfortunately, BO responds poorly to therapy (see Chapter 50).

DIFFUSE PANBRONCHIOLITIS

Diffuse panbronchiolitis is a rare form of bronchiolitis involving the upper and lower respiratory tracts that is seen primarily in Japan and only rarely outside the Far East. Genetic factors, specific human leukocyte antigen (HLA) haplotypes, are thought to contribute to the pathogenesis and geographic distribution of this disease. Such patients typically present with chronic sinusitis, cough productive of copious sputum, dyspnea, wheezing, and weight loss. Airflow obstruction is a common feature, and HRCT may show diffusely thickened and dilated bronchi or tree-in-bud opacities corresponding to bronchiolitis. Confirming this diagnosis is important, because diffuse panbronchiolitis often improves with macrolide antibiotics.

LYMPHANGIOLEIOMYOMATOSIS

Lymphangioleiomyomatosis is a rare disorder affecting women almost exclusively.¹¹³ It is caused by a mutation in the tuberous sclerosis-1 or -2 gene, either sporadically or in the setting of tuberous sclerosis, resulting in the proliferation of interstitial smooth muscle cells and pulmonary cyst formation. Other clinical characteristics include renal angiomyolipomas and chylous effusions. Lymphangioleiomyomatosis is also characterized by airflow obstruction and spontaneous pneumothoraces. Therefore it is not infrequently mistaken for emphysema. However, an expert radiologist should be able to distinguish pulmonary cystic changes from emphysematous holes. The presence of other characteristic clinical features can be helpful in the diagnosis.

EPIDEMIOLOGY

COPD is currently the third leading cause of death in the United States¹¹⁴ and is projected to be the third leading cause of death worldwide by 2020.¹¹⁵ To give some sense of its impact, in 2006, COPD killed more American women than breast cancer and diabetes combined.¹¹⁶ COPD is also associated with significant morbidity. In the United States in 2006, COPD was responsible for an estimated 672,000 hospitalizations. The cost for caring for patients with COPD continues to increase, with an estimated \$49.9 billion spent in 2010.¹¹⁷ A significant proportion of these costs are attributable to acute exacerbations.¹¹⁸ COPD patients also have significant comorbidities that likely contribute to their increased cost of care. (For a more detailed discussion of COPD epidemiology, see Chapter 43.)

ENVIRONMENTAL INFLUENCES

The primary risk factor for the development of COPD is tobacco smoke exposure. Data suggest the prevalence of COPD in smokers is approximately 20% compared with 4% in nonsmokers.¹¹⁹ While not all smokers develop COPD, smokers still lose lung function in a dose-dependent manner.¹²⁰ Furthermore, smoking is associated with reduced life expectancy. The life expectancy for nonsmokers with COPD is modestly reduced; for current and former smokers with COPD, life expectancy is significantly reduced.¹²¹ Data from smoking cessation studies provide additional support for the association between smoking and COPD. The rate of FEV₁ decline is greatest in patients who smoke the most and is lowest in those who quit smoking.¹²² “Second hand smoke” or “environmental tobacco smoke” exposure has also been associated with increased risk for COPD.¹²³

Data from the Third National Health and Nutrition Epidemiological Survey put the prevalence of COPD in nonsmokers in the United States at approximately 6.6%,¹²⁴ although worldwide estimates for non-tobacco-related COPD range from 20% to 50% of all COPD cases depending on locale.¹²⁵ Factors such as traffic, outdoor pollution, and biomass smoke contribute to these findings.^{126,127} Smoke generated from biomass fuels is an important etiology of COPD, particularly in women in developing countries where biomass fuels are used for cooking.¹²⁸ In total it has been estimated that the attributable fraction of COPD due to cigarette smoking is approximately 80% to 90%,¹²⁹ while occupational exposures including gas, dust, and fumes contribute to the population burden of COPD by approximately 15%.¹²⁹

HOST FACTORS

Genetics

COPD results from an interaction between environmental exposures, most notably tobacco smoke, and increased genetic susceptibility. Family history of COPD also appears to be a risk factor for COPD development, independent of family smoking history, personal smoking history, or childhood environmental tobacco exposure.¹³⁰ The strongest genetic risk factor that has been identified is mutation in the

A1AT protease, resulting in a deficiency in the resultant protein (discussed previously). Unfortunately, the combination of A1AT deficiency and smoking leads to a marked acceleration in loss of lung function compared with the presence of either alone.¹³¹ The discovery of A1AT deficiency more than 40 years ago raised hopes that other COPD susceptibility genes would be identified rapidly. However, it is only recently that data from genome-wide association studies have led to consistent associations between new genetic loci and COPD susceptibility. Data from genome-wide association studies provide good evidence that the cholinergic nicotinic acetylcholine receptor *CHRNA3/5*, *HHIP*, and *FAM13A* loci all appear to be associated with disease susceptibility.¹³² In particular, the *CHRNA3/5* locus appears to be associated with increased smoking intensity and emphysema in individuals with COPD. The *HHIP* locus has been associated with the systemic components of COPD, frequency of COPD exacerbations, and FEV₁/FVC ratio.^{133,134} The *FAM13A* locus has also been associated with FEV₁/FVC.¹³³ Efforts to identify other genetic loci are ongoing in multiple cohorts. (For more discussion of the genetics of COPD, see Chapter 45.)

Other Modifying Factors

Gender is an important clinical feature that also may influence multiple aspects of COPD, including susceptibility. Conflicting data have been published regarding whether women are more susceptible to developing COPD adjusted for smoking exposure.¹²⁸ However, the most recent epidemiologic data suggest the prevalence of COPD worldwide by gender is becoming increasingly similar and likely reflective of cigarette and other environmental exposures.¹³⁵ Gender may modify other aspects of the disease, however. In general, women report more dyspnea, similar severity of cough, but less sputum than men.¹³⁶ Recent data also suggest that COPD exacerbations are more frequent in women, but whether this represents a difference in disease biology or reporting patterns is unknown.^{137,138} Maternal smoking and female gender have also been associated with severe, early-onset COPD.¹³⁹

Several other factors have been identified that modify COPD prevalence and presentation. Lower socioeconomic status significantly increases morbidity and mortality of COPD.¹⁴⁰ The reasons for this are not understood with certainty but may be connected to differences in access to care. Less data are available on the influences of race although, within the United States, there appears to be increasing prevalence of COPD among African Americans as well as a significant increase in mortality.¹⁴¹ African Americans may also be more susceptible to the harm from tobacco smoke than whites.¹⁴² Exacerbations during hospitalization may also be more frequent in African Americans.¹⁴³ Cultural, socioeconomic, and biologic influences could all contribute to these findings.

TREATMENT

Until recently, treatment of COPD was focused entirely on relief of symptoms, because treatment options were few and were believed to be largely ineffective. In fact, the literature reported that the only interventions that changed the

natural history of COPD were smoking cessation,^{122,144} and oxygen in patients with hypoxemia.^{145,146} More recently, however, clinical trials have demonstrated that pharmacologic treatments can prevent or attenuate acute exacerbations of COPD, and the data suggest that some can slow the inexorable loss of lung function over time that is the hallmark of COPD.¹⁴⁷⁻¹⁴⁹ These observations have appropriately shifted the focus to a more proactive approach, aiming to identify patients earlier in the course of their disease and to implement treatment regimens that would not only relieve symptoms but also prevent exacerbations, prevent disease progression, improve exercise tolerance, and improve quality of life.

GENERAL PRINCIPLES OF TREATMENT

Goals of treatment of COPD are to *reduce symptoms*, which includes relief of dyspnea, improved exercise tolerance, and improved health status, to *reduce risk* by preventing and treating exacerbations, preventing disease progression, and reducing mortality, and, at the same time, to *minimize the adverse effects* of medications.

Reduction of Risk Factors

In the case of COPD, risk reduction refers to interventions that may decrease the likelihood of developing the disease, slow disease progression, decrease exacerbations, and reduce mortality. Although our knowledge of the factors that contribute to each of these is limited, there are substantial data on some factors that contribute to each of these.

Smoking Cessation. Throughout the developed world, cigarette smoking is the most important risk factor for the development of COPD. Public health and educational programs aimed at discouraging people from smoking (“primary prevention”) and efforts to help active smokers stop are probably the most important intervention for COPD. In their landmark publication in 1977,¹⁴⁴ Fletcher and Peto showed that, in patients with COPD who stopped smoking, the accelerated loss of lung function slowed until it more closely paralleled the annual decrement seen in nonsmokers (Fig 44-7) (see Chapter 43). Nearly 2 decades later, the National Institutes of Health–sponsored Lung Health Study demonstrated that in smokers with COPD, smoking cessation reduced the rate of decline in lung function, whereas inhaled bronchodilator did not.¹²² In a 14.5-year follow-up to the Lung Health Study, Anthonisen and colleagues reported that the lung-function benefit continued for persistent quitters; there was also a mortality (all cause) benefit for those who maintained abstinence. Perhaps more important, even those whose smoking cessation was intermittent experienced a benefit compared with continued smokers.^{150,151} Smoking cessation education and support should be offered to every patient with COPD, at every visit. (For more detail on smoking cessation, see Chapter 46.)

Biomass Fuel. In the developing world, cigarette smoke is less of an issue than is exposure to biomass fuel, used for cooking and heating. The exposure is particularly great for women and their young children, who may spend the

Figure 44-7 Fletcher Peto curve of the natural history of COPD. Lung function increases with growth in childhood and adolescence. Fetal and childhood events can affect lung growth and development, resulting in reduced maximally attained lung function, for convenience shown here as an FEV₁ of 4 L. Actual predicted values depend on height and gender. After growth is completed, lung function remains constant for some time, the “plateau phase,” after which lung function declines at an accelerating rate with age. Smoking reduces the duration of the plateau phase and accelerates the rate of lung function loss. Smoking cessation early in the course of the disease can reduce the rate of lung function loss to that of a non-smoker. Patients typically present with symptoms when lung function declines below 50% of that in young adulthood but may have limitation much earlier. (See text for details.)

greater part of each day indoors with an unvented fire, fueled by wood, dung, or kerosene. Such exposure has been associated with chronic bronchitis and COPD.¹⁵²⁻¹⁵⁵ Guarnieri and colleagues showed that something as simple as a vented stove can decrease gene expression for markers of inflammation in sputum.¹⁵⁶ (For more information, see Chapter 74.)

Environmental Controls. In addition to active and secondary smoke exposure, allergens and air pollutants may have an impact on COPD. Catastrophic air pollution events in the Meuse Valley, Donora, and London speak to the potential for air quality to impact people with lung disease. In addition, a growing body of evidence suggests that long-term exposure to even low levels of air pollution increase the risk for COPD.¹⁵⁷ Also, people with COPD who also have allergic disease have higher levels of respiratory symptoms and are at higher risk for COPD exacerbations.¹⁵⁸ As a consequence, people with COPD should avoid noxious exposures, heed air quality warnings, and be cautious of ongoing occupational exposures.

Prevention of Respiratory Infections. A significant proportion of COPD exacerbations are triggered by respiratory infections. Although there are some data to suggest that patients with COPD are more susceptible to respiratory infections because of impaired mucociliary clearance, a more important issue is that those with COPD are more susceptible to the *consequences* of respiratory tract infections. As a general rule, every patient with COPD should be immunized annually against influenza, which is effective at reducing the incidence of influenza regardless of the severity of COPD,¹⁵⁹ and has been demonstrated to reduce mortality in older adults.^{160,161} In addition all should be

vaccinated against *S. pneumoniae*. Despite a belief that older patients with COPD might not respond well to immunization, pneumococcal vaccines have been shown to work in this population.^{162,163} Chronic antibiotics for prophylaxis are not a part of standard care for COPD because early trials showed they were not useful.¹⁶⁴⁻¹⁶⁷ However, more recent trials with erythromycin and moxifloxacin have demonstrated a reduction in exacerbations.^{168,169} There has been a particular interest in macrolide antibiotics, because of their demonstrated value in diffuse panbronchiolitis and in cystic fibrosis, and because they may have anti-inflammatory as well as antimicrobial properties. In a prospective, randomized, double-blind trial of 1142 patients with exacerbation-prone COPD, the National Heart, Lung, and Blood Institute's COPD Clinical Research Network found that daily azithromycin for 1 year decreased the frequency of exacerbations by 27% and improved quality of life.¹⁷⁰ Enthusiasm for this approach has been tempered by the small risk of ototoxicity and by the potential for QTc prolongation by macrolides. Data suggest that screening subjects for history of cardiac disease and obtaining ECGs prior to starting macrolides reduces the risk of cardiac rhythm disturbance.¹⁷¹ Thus, in selected patients who neither have cardiac disease nor take concomitant medications that affect the QTc interval and who experience frequent exacerbations with the attendant morbidity and mortality, the small risk of azithromycin is probably warranted.

Prevention of Exacerbations. Exacerbations of COPD are sentinel events and are closely associated with disease progression. Increasing severity of COPD is associated with increased exacerbations and need for hospitalization, but for every stage of severity, severe exacerbations are associated with increases in short-term and long-term all-cause mortality.¹⁷² Exacerbations have an independent negative effect on prognosis, and mortality increases with the frequency of hospitalizations. In one study of 305 men with COPD, only 20% to 30% of patients who were readmitted for exacerbations survived 5 years.¹⁷³ Although supporting data are lacking, the hope is that, by preventing exacerbations, lung function may be preserved and deterioration prevented. ICS, long-acting β -agonists, long-acting muscarinic antagonists, and macrolide antibiotics have all been shown to reduce exacerbations. Unfortunately, even patients taking these medications may still experience as many as 1.4 exacerbations per year.¹⁷⁴

PHARMACOTHERAPY

The goal of treatment was once primarily symptom relief. Now that goal includes an attempt to improve lung function or slow the loss of lung function, and to prevent exacerbations. Most medications for COPD are administered by inhalation. Standard therapy consists of inhaled bronchodilators, either β -agonists or antimuscarinics (anticholinergics), and ICS. Oral agents, used less commonly, include methylxanthines (e.g., theophylline), phosphodiesterase-4 inhibitors (e.g., roflumilast), and corticosteroids (prednisone or prednisolone).

The choice of medications should be based on an assessment of the severity of airflow obstruction, symptoms, fre-

Figure 44-8 GOLD classification system.³⁴ When assessing risk, choose the highest risk according to airflow limitation or exacerbation history. (One or more hospitalizations for COPD exacerbations should be considered high risk.) (Global Strategy for the Diagnosis, Management and Prevention of COPD, Global Initiative for Chronic Obstructive Lung Disease (GOLD) 2014. Available from: <http://www.goldcopd.org/>.)

quency and severity of exacerbations, and patient's functional limitation, as well as on the availability and local cost of medications. Formerly, medication decisions were based primarily on severity of airflow obstruction; guidelines now, as exemplified by GOLD,¹⁷⁵ emphasize a metric that includes obstruction (GOLD grade), based on FEV₁ percent predicted (see Table 44-2), symptoms (based on either the Medical Research Council dyspnea scale¹⁷⁶ or the COPD Assessment Test¹⁹), and risk of exacerbations. Using this tool, patients can be categorized into class A, B, C, or D (Fig. 44-8), and GOLD provides specific treatment recommendations for each category (Table 44-3).

Bronchodilators

Bronchodilators are recommended for all patients with COPD. Pharmaceutical classes of bronchodilators include β -agonists, antimuscarinics (anticholinergics), and methylxanthines. Unlike asthma, where bronchodilator reversibility is part of the definition, airflow obstruction in COPD is often thought of as "irreversible." This is not, however, completely true. Although the diagnosis of COPD requires airflow obstruction that persists after bronchodilators, most patients with COPD demonstrate some improvement in spirometry. This response can vary from day to day.¹⁷⁷ In one study of 1552 patients with COPD who were tested with albuterol, ipratropium, or the combination on four occasions over 3 months, only 37% to 56% had 15% or better improvement in FEV₁ on all four test dates, but 90% or more had greater than or equal to 15% reversal on at least one occasion.¹⁷⁸ Therefore, even patients who do not respond to bronchodilator testing in the pulmonary function laboratory should be given a clinical trial of bronchodilators. Although the increase in FEV₁ may be modest, it may be sufficient to improve lung emptying and, by this mechanism, reduce dynamic hyperinflation.¹⁷⁹⁻¹⁸¹ In multiple studies, bronchodilators have been shown to reduce dyspnea and increase exercise tolerance in patients with chronic stable COPD.^{182,183}

Table 44-3 Pharmacologic Management of COPD*

Patient Group	Recommended First choice	Alternative Choice	Other Possible Treatments†
A	SAMA prn or SABA prn	LAMA or LABA or SABA and SAMA	Theophylline
B	LAMA or LABA	LAMA and LABA	SABA and/or SAMA Theophylline
C	ICS + LABA or LABA	LAMA and LABA or LABA and PDE4-inh. or LABA and PDE4-inh.	SABA and/or SAMA Theophylline
D	ICS + LABA and/or LABA	ICS and LABA and LABA or ICS and LABA and PDE4-inh. or LABA and LABA or LABA and PDE4-inh.	Carbocysteine SABA and/or SAMA Theophylline

*Medications in each box are mentioned in alphabetical order, and therefore not necessarily in order of preference.

†Medications in this column can be used alone or in combination with other options in the Recommended First Choice and Alternative Choice columns.

Abbreviations are defined in the text.

β-Adrenergic Agonists

These medications bind directly to β-receptors located on airway smooth muscle and dilate the airway. Less prominent effects include increased ciliary beat frequency that promotes mucus transport along the mucociliary escalator¹⁸⁴ and improved respiratory muscle endurance.¹⁸⁵ β-agonists are available in both short-acting and long-acting preparations, and can be administered by inhalation, orally, subcutaneously, or intravenously. For treatment of COPD, β-agonists should only be given as inhaled aerosols, because the other routes are associated with an unacceptably high risk of systemic adverse effects.

Short-acting beta agonists (SABAs) include albuterol (salbutamol), levalbuterol, terbutaline, and fenoterol. Albuterol is a racemic mixture of both (R)- and (S)-enantiomers of albuterol; levalbuterol is the (R)-enantiomer alone. The (R)-enantiomer is thought to be responsible for bronchodilation while the (S)-enantiomer is believed to cause tremor, tachycardia, and perhaps airway inflammation. Thus, levalbuterol would be expected to be better tolerated than albuterol. In fact, for most patients with stable COPD who use their short-acting β-agonist for symptom management, the added advantage of levalbuterol over albuterol¹⁸⁶ is probably not significant.¹⁸⁷ Albuterol is also available in combination with ipratropium (a muscarinic antagonist). Terbutaline inhalers are no longer sold in the United States; fenoterol is available in many parts of the world, but not in the United States.

Short-acting β-agonists for inhalation are available in solution for administration by nebulizer, as well as by metered-dose inhaler and *dry powder inhaler* (DPI). The

combination of albuterol and ipratropium is available in a soft mist inhaler. Many studies have shown that metered-dose inhalers, DPIs, and soft mist inhalers are as effective as nebulizers in patients who are able to use the devices properly. Unfortunately, the proper technique for using different devices is not the same, and patients need detailed instruction and periodic assessment of their technique. In addition, DPIs require a much higher inspiratory flow than do metered-dose inhalers and some patients with moderate-to-severe COPD may not be able to generate adequate flows. For these individuals and for those whose medical or mental status makes coordinated breathing efforts difficult, nebulized β-agonists may be preferable.¹⁸⁸

The major advantage of short-acting β-agonists is their rapid onset of action, within 5 to 15 minutes after inhalation. Their effects last for 2 to 6 hours. As noted earlier, most patients with COPD demonstrate a modest improvement in FEV₁, and many studies and meta-analyses support their use for COPD.¹⁸⁹ The combination of albuterol and ipratropium results in greater and more sustained improvement in lung function than either drug alone.¹⁹⁰⁻¹⁹² When used at the recommended doses, inhaled short-acting β-agonists are thought to be safe. The major adverse effects include tremor, anxiety, tachycardia, and hypokalemia. A recent retrospective case-control cohort study of more than 70,000 patients with COPD from Quebec suggested that the new use of short- or long-acting beta agonists was associated with increased risk for arrhythmias,¹⁹³ but the study did not account for multiple potential confounders. Adverse effects are dose-dependent and are less common with inhaled compared with systemic dosing, and when inhaler technique is optimized. Fortunately, tachyphylaxis to the systemic side effects of β-agonists is greater than tachyphylaxis to the bronchodilator effect.

Long-acting β-agonists (LABAs) typically produce bronchodilation that lasts for 12 hours or more. Salmeterol was the first LABA to be studied extensively. Its onset of action is much slower than that of albuterol, on the order of 20 to 30 minutes. Formoterol has a similar duration of action, but an onset of action that is nearly identical to albuterol. Both salmeterol and formoterol must be taken twice daily. Arformoterol is the (R)-enantiomer of formoterol. Indacaterol has a rapid onset and a duration of action of nearly 24 hours, and thus requires only once daily dosing. The bronchodilator effect of indacaterol is greater than that of salmeterol or formoterol. Vilanterol is another LABA with a rapid onset of action and a duration of action of approximately 24 hours. It is not used as monotherapy, but has recently been approved in the United States and in Europe for use in combination with the ICS fluticasone.

Many studies have demonstrated a benefit of LABAs in patients with stable COPD.^{65,194-201} Salmeterol and formoterol significantly improve lung function, dyspnea, quality of life, and the rate of exacerbations.^{65,202-206} Salmeterol has been shown to reduce hospitalizations.⁶⁵ Indacaterol improves dyspnea and health status, and reduces exacerbations.²⁰⁷⁻²¹⁰ The adverse effects reported with LABAs are similar to those described for short-acting β-agonists. Of note, the association of LABA use with deaths that raised concern in the asthma community (see Chapter 42) has not been seen for COPD, and monotherapy with an LABA appears to be both safe and efficacious.

LABAs are frequently combined with an ICS in the same inhaler, and currently available preparations include salmeterol/fluticasone, formoterol/budesonide, formoterol/mometasone, and vilanterol/fluticasone. Many studies have shown that combination therapy is often more effective than either agent alone, and various guidelines provide recommendations for how and when to escalate treatment beyond short-acting bronchodilators.

Antimuscarinics

Antimuscarinics, also known as anticholinergics or muscarinic antagonists, block the effects of acetylcholine on M3 muscarinic receptors on airway smooth muscle. Anticholinergics were used historically, long before β -agonists, in the form of stramonium and belladonna alkaloids,^{211,212} then atropine. The newer quaternary amines such as ipratropium and glycopyrrolate, as well as tiotropium and aclidinium, are better tolerated because they do not cross the blood-brain barrier. In addition, both tiotropium and aclidinium have pharmacokinetic selectivity for the M3 receptor and dissociate more rapidly from M2 receptors, which are found on cholinergic nerve terminals and inhibit acetylcholine release.²¹³ Thus, the relative lack of M2 binding by these muscarinic antagonists may allow acetylcholine to bind to M2 receptors, thereby inhibiting further acetylcholine release and reducing bronchoconstriction.²¹⁴

Short-acting muscarinic antagonists (SAMAs) include ipratropium and oxitropium. They increase FEV₁ with an onset of action of 10 to 15 minutes and a duration of action of 4 to 6 hours. Ipratropium improves lung function, increases exercise capacity, decreases dyspnea, and decreases cough.²¹⁵ The magnitude of bronchodilation with ipratropium is comparable to that seen with albuterol but, when used in combination, their effects are additive and the duration is longer.¹⁹⁰⁻¹⁹²

Long-acting muscarinic antagonists (LAMAs) include tiotropium and aclidinium, which are slower in onset than ipratropium, but last longer, with bronchodilation lasting at least 12 hours after aclidinium²¹⁶ and more than 24 hours after tiotropium.²¹⁷⁻²¹⁹ In the United States, tiotropium is available as the HandiHaler DPI; in Europe, it is available as a soft-mist inhaler (RespiMat). Aclidinium is provided in a DPI that registers when a dose is inhaled. Tiotropium decreases symptoms, improves health status, and reduces exacerbations by 20% to 25%^{220,221} and hospitalizations.²¹⁸ It appears to improve the effectiveness of pulmonary rehabilitation, perhaps by decreasing dynamic hyperinflation.²²² When compared head-to-head with salmeterol, tiotropium increased time to first exacerbation and reduced the annual rate of exacerbations more than did salmeterol.²²³ Although less data are available for aclidinium, its effects on lung function and on dyspnea appears to be similar to those of tiotropium.²¹⁶

In general, both short- and long-acting muscarinic antagonists have good safety profiles. The most common side effects are dry mouth and urinary retention. Medication that contacts the eye, either by hand contact or by aerosolization, can cause blurred vision and can precipitate glaucoma. A retrospective database review²²⁴ and a meta-analysis of ipratropium and tiotropium in COPD²²⁵ suggested that anticholinergic therapy was associated with an

increased risk of cardiovascular death, myocardial infarction, and stroke. However, a prospective study of almost 6000 patients with COPD who were treated with tiotropium or placebo found no increased risk of cardiovascular events or mortality,^{226,227} and a long-term study of more than 17,000 patients with COPD, designed specifically to examine safety, concluded that tiotropium administered by the new soft-mist Respimat device had a safety profile similar to tiotropium delivered by the current DPI HandiHaler device in patients with COPD and was not associated with an increased risk of death.²²⁸

Methylxanthines

Methylxanthines are nonselective inhibitors of phosphodiesterase, and by this mechanism have a modest bronchodilator effect.^{205,229,230} Theophylline is the most commonly used methylxanthine and, in stable COPD, its effect is greater than that of placebo but less than that of LABAs or LAMAs. In addition to its bronchodilator effect, theophylline is reported to improve inspiratory muscle function²³¹⁻²³³ and to have anti-inflammatory effects.²³⁴ Its effect on reducing symptoms is greater than its effect on airway function, suggesting that these alternative mechanisms may be important. Because theophylline is a nonselective phosphodiesterase inhibitor, its actions are not all beneficial. The major adverse effects are insomnia, nausea, vomiting, cardiac arrhythmias, and seizures. These toxicities are dose-dependent, but the onset of severe adverse events (e.g., ventricular arrhythmias, seizures) may not be preceded by nausea or insomnia. In addition, blood levels are affected by age, by liver disease, by congestive heart failure, and by many drug interactions. To minimize toxicity, current guidelines recommend target blood levels of 5 to 10 $\mu\text{g/mL}$ rather than 15 to 20 $\mu\text{g/mL}$ as was done previously. Because of its narrow therapeutic index and modest benefits, theophylline is not recommended as a first line drug, but can serve as an alternative for patients intolerant of LABAs and LAMAs or in settings where these drugs are too expensive.

Phosphodiesterase-4 Inhibitors

Phosphodiesterase-4 (PDE-4) inhibitors act by blocking the breakdown of cyclic adenosine monophosphate. By this mechanism, they decrease airway inflammation; they have no direct bronchodilator activity. Roflumilast is an oral PDE-4 inhibitor that has been approved for patients with chronic bronchitis and a history of exacerbations.¹⁴ In a meta-analysis of 23 randomized trials of two different PDE-4 inhibitors (roflumilast and cilomilast), the PDE-4 inhibitors reduced exacerbations (OR 0.78, 95% CI 0.72 to 0.85) and produced a modest increase in FEV₁ (50 mL, 95% CI 39 to 52).²³⁵ When roflumilast was added to salmeterol or tiotropium, the prebronchodilator FEV₁ increased.^{14,15} Because its effect on exacerbations is much greater than its effect on airway function, guidelines recommend that roflumilast be used in combination with a long-acting bronchodilator.¹⁷⁵ Use of PDE-4 inhibitors has been limited by side effects. The most common are nausea, anorexia, abdominal pain, diarrhea, weight loss, sleep disturbances, and headache.^{14,15,236} Monitoring weight during treatment is warranted.¹⁷⁵

Corticosteroids

Inhaled Corticosteroids. Airway as well as systemic inflammation are critical components of the pathogenesis of COPD.²³⁷⁻²³⁹ Therefore, corticosteroids, with their anti-inflammatory effects, are an appealing intervention. ICS offer the additional advantage of minimizing systemic exposure. Early studies of ICS sought unsuccessfully to alter the natural history of COPD. However, ICS have been shown to improve symptoms, lung function, and quality of life, and to reduce the frequency of COPD exacerbations, especially in patients with an FEV₁ less than or equal to 60% of predicted. The improvement in FEV₁ achieved with ICS (50 to 100 mL) is typically less than that observed with bronchodilators.^{147,148} The reduction of exacerbations by ICS is more significant and is comparable to that observed with LABAs or LAMAs (approximately 20% to 25%).²⁴⁰⁻²⁴² Guidelines recommend that ICS be used in combination with a long-acting bronchodilator in subjects who are prone to exacerbations, but that they not be used as monotherapy.¹⁷⁵ Four large trials in which patients with COPD were treated with ICS for 3 to 5 years failed to reduce the loss of lung function over time.^{147,148,243,244} However, in a post hoc analysis of the TORCH trial in which 6112 subjects with moderate-to-severe COPD were randomly treated for 3 years with placebo, fluticasone, salmeterol, or the fluticasone/salmeterol combination, Celli and colleagues²⁴⁵ reported that each active treatment arm reduced the rate of decline in FEV₁. Whether this benefit reflects the reduction in exacerbations or a more direct effect on the airway, perhaps by decreasing inflammation, is not known.

ICS are relatively safe, especially in comparison to systemic corticosteroids. The most common adverse effects are oral candidiasis (thrush) and dysphonia, both of which can be minimized by careful inhalation technique followed by rinsing the mouth and gargling.^{147,148} Increased skin bruising is probably a manifestation of capillary fragility. Reduced bone density has been reported after long-term treatment with triamcinolone,²⁴⁶ but studies with budesonide and fluticasone have not found similar results, perhaps because these patients with COPD had a high prevalence of osteoporosis at baseline.^{247,248} Finally, although ICS clearly reduce the frequency of exacerbations in COPD, they have been associated with an increased incidence of pneumonia.⁶⁵

Systemic Corticosteroids. With rare exceptions, the use of systemic corticosteroids should be reserved for the treatment of exacerbations. In patients with stable disease, even when severe, the risk of adverse effects is probably greater than the likelihood of benefit. Chronic use of systemic corticosteroids is associated with increased mortality,^{249,250} which may reflect corticosteroid effects or the underlying severity of the COPD. Occasionally, in exacerbation-prone patients who require frequent courses of high dose systemic corticosteroids, a very low daily dose of corticosteroids may protect against exacerbations and thereby reduce the total annual steroid exposure. If this unusual approach is followed, the lowest possible dose of corticosteroids should be used. Spirometric stability may be useful in encouraging patients who are experiencing nonpulmonary benefit that dose reduction is safe.

Combination Therapy

Patients who remain symptomatic after a period of treatment with a single long-acting bronchodilator (either LABA or LAMA) may benefit from addition of a second drug. Choices include either an ICS or a second long-acting bronchodilator from the other pharmacologic class; literature to inform this decision is not clear. ICS should probably be considered as the first addition in patients with evidence of airway inflammation and those with frequent exacerbations. In two large trials, combination therapy improved outcomes significantly compared to each of the other treatment arms alone (placebo LABA, ICS, LAMA). In the TORCH trial of 6112 patients with moderate-to-severe COPD, the combination of salmeterol/fluticasone improved lung function, health status, and exacerbations more than either agent alone⁶⁵ and was cost effective.²⁵¹ In the INSPIRE trial, 1323 patients with severe COPD were randomly treated with salmeterol/fluticasone or tiotropium for 2 years.²⁵² There was no difference in exacerbations, but mortality was less in the salmeterol/fluticasone group and health status was better. Pneumonia was more frequent in the salmeterol/fluticasone group. Combinations of formoterol/budesonide, formoterol/mometasone, and vilanterol/fluticasone have also been shown to improve some clinical outcomes.

While many studies have compared the ICS/LABA combination to its individual components, fewer studies have compared ICS/LABA to LABA/LAMA. Rabe and colleagues²⁵³ randomized 592 patients with moderate-to-severe COPD to tiotropium/formoterol or fluticasone/salmeterol. After 6 weeks, FEV₁ was larger in the tiotropium/formoterol group and the use of rescue medications did not differ.²⁵³

Finally, guidelines suggest “triple inhaler therapy” for subjects whose symptoms are not controlled by any of the combinations already described.¹⁷⁵ This recommendation is in part empirical, because each of the drugs or combinations have been shown to be effective. However, several retrospective cohort studies have described decreased mortality, and fewer exacerbations and hospitalizations with triple therapy.^{254,255} The only prospective data comes from the UPLIFT trial, in which patients were randomized to receive “usual care” with or without tiotropium. In those patients who were already taking an ICS and a LABA (two thirds of the group), the addition of tiotropium significantly improved lung function, reduced exacerbations, and improved health-related quality of life.²²⁶ Further studies are needed to define the role of triple-therapy.

Stepwise Pharmacologic Management

We have made enormous progress from the time, not long ago, when we had few drugs for COPD in our therapeutic armamentarium. Now there are many pharmaceutical categories that have been shown to improve outcomes in COPD. Often there are many choices within each drug class, and a variety of ways to progress through a therapeutic algorithm. The GOLD guidelines provide a framework for making these decisions.

In the past, recommendations for pharmacologic treatment were based primarily on spirometry, and Table 44-2 shows the GOLD classification scheme based on lung

function. Recognizing that FEV₁ alone is a poor descriptor of disease status, the GOLD committee revised the approach to include symptoms and future risk of exacerbations, in addition to lung function (see Fig. 44-8). Based on these three variables, patients are assigned to groups A, B, C, or D, and recommendations for initial management are provided for each group (see Table 44-3).

Antioxidants and Mucolytics

Increased mucus production by hypertrophied and hyperplastic airway submucosal glands and goblet cells, together with impaired mucociliary clearance and cough are frequent in patients with COPD. Although mucolytics have been evaluated in a number of long-term studies in COPD, the results are mixed and, in those studies demonstrating benefit, the effect is modest.²⁵⁶⁻²⁵⁸ *N-acetylcysteine* (NAC) is a mucolytic and antioxidant that has been tested for its ability to slow the decline in lung function and prevent exacerbations. In the BRONCUS study, 523 patients at 50 centers were randomly assigned to 600 mg NAC or placebo daily. Patients were followed for 3 years. Neither the yearly rate of decline in FEV₁ nor the number of exacerbations per year differed between the NAC and the placebo group. However, subgroup analysis of those subjects who were not treated with an ICS suggested that NAC reduced exacerbations and hyperinflation.²⁵⁹ A Cochrane review of 30 trials that included more than 7000 patients treated with NAC or other mucolytics concluded that there was a small effect on exacerbations, but no effect on quality of life.²⁶⁰ In its 2014 revision, the GOLD panel advised against the widespread use of these agents.¹⁷⁵

LEUKOTRIENE MODIFIERS

Although the 5-lipoxygenase inhibitor zileuton and the cysteinyl leukotriene antagonists montelukast and zafirlukast are sometimes used for COPD, there are no data to support their use and guidelines do not recommend their use.¹⁷⁵

NONPHARMACOLOGIC TREATMENT

Mucus Clearance

In patients with mucus hypersecretion and airflow obstruction, it may be very difficult to mobilize secretions. Maneuvers such as controlled cough²⁶¹ and the huff cough²⁶² can be helpful. In the former, patients take a deep breath, hold their breath for a few seconds, then cough two or three times with their mouth open and without taking another breath. The sequence is then repeated several times. Huff coughing involves one or two forced expirations starting at mid-lung volume and performed with the glottis open. Mucus clearance can also be facilitated by having patients breathe or cough through a device that generates high amplitude oscillations,²⁶³ or with an external percussive device. These maneuvers are considered safe, but data supporting their use is limited.²⁶⁴⁻²⁶⁷

Oxygen

Two landmark studies conducted more than 30 years ago demonstrated the value of long-term oxygen therapy in

patients with COPD and hypoxemia. The National Institute of Health's *Nocturnal Oxygen Therapy Trial* (NOTT) randomized 203 patients with COPD and hypoxemia to receive oxygen either for 12 hours overnight or for 24 hours/day for at least 12 months.¹⁴⁵ Overall mortality in the nocturnal oxygen group was 1.94 times that in the continuous oxygen group ($P = 0.01$). Almost simultaneously, the British Medical Research Council compared the effect of oxygen administered for 15 hours/day with no oxygen (control) in 87 patients with COPD, hypoxemia, carbon dioxide retention, and heart failure. Forty-five percent of the oxygen-treated patients died during the 5-year follow-up period compared with 67% of the control group.¹⁴⁶ In addition to this survival benefit, administration of oxygen for at least 15 hours per day improves quality of life and neuropsychiatric metrics, reduces erythrocytosis, and improves pulmonary hemodynamics in patients with COPD and hypoxemia.^{145,268,269}

Indications for Oxygen. Based on these data, guidelines recommend long-term administration of oxygen (>15 hours/day) to patients with COPD with resting hypoxemia. Criteria include arterial PO₂ less than 55 mm Hg, or arterial SO₂ less than 88% while breathing room air at rest. For those whose resting arterial PO₂ is between 56 and 59 mm Hg, long-term oxygen treatment is indicated if they demonstrate erythrocytosis (hematocrit $\geq 55\%$) or cor pulmonale. Following an exacerbation or another acute respiratory event, patients often have hypoxemia that resolves slowly over 1 to 2 months. For this reason, patients given oxygen as they are recovering should be reevaluated after approximately 1 month to determine if they continue to meet criteria for long-term oxygen treatment.

Oxygen During Exercise. Patients whose arterial PO₂ or SpO₂ are borderline at rest may develop worsening hypoxemia with exercise. This is especially true for patients with emphysema and a low diffusing capacity. Supplementary oxygen improves exercise endurance,^{270,271} and even patients without hypoxemia may improve their exercise capacity with supplementary oxygen.²⁷² However, long-term benefits of oxygen in this patient group are unknown. The National Heart, Lung, and Blood Institute is sponsoring the *Long-term Oxygen Treatment Trial* (LOTT) that will examine mortality, hospitalizations, quality of life, and a variety of other outcomes in 737 patients with COPD and SpO₂ between 89% and 93% at rest, or greater than 94% at rest with a desaturation to less than 90% with exercise.²⁷³

One of the goals of oxygen therapy is to permit patients to remain active. Ambulatory oxygen systems are intended to provide a lightweight, portable source of oxygen that can be carried as the patient pursues activities of daily living. Unfortunately, patients are often provided with "portable" systems that are not really conducive to ambulation. The standard E-cylinder, for example, weighs 22 pounds and must be pulled along on a bulky wheeled cart. Various lightweight oxygen reservoirs do exist, weighing as little as 4 pounds; portable oxygen concentrators are another lightweight option. Health care providers must specify to oxygen vendors which ambulatory system they want for their patients.

Oxygen During Sleep. Just as they do with exercise, patients with COPD may experience a significant drop in arterial oxygen tension during sleep, due to a combination of increases in ventilation-perfusion mismatch and a change in ventilatory pattern.²⁷⁴ In patients who are not hypoxemic at rest, the long-term consequences of these episodes of nocturnal hypoxemia are unknown, as are the benefits of long-term oxygen for these patients. Although many clinicians prescribe nocturnal oxygen for these patients, there is no evidence to support this approach. The LOTT trial will provide information on this clinical subgroup.

Oxygen for Air Travel. When flying at altitudes greater than 12,000 feet, aircraft are pressurized to protect passengers and crew from hypoxemia and other manifestations of altitude sickness (see Chapter 77). The *Federal Aviation Administration* (FAA) mandates that the cabin altitude must not exceed 8000 ft. Although this pressurization is sufficient to prevent most barotrauma and altitude sickness, it does not eliminate the possibility of hypoxemia. Arterial PO_2 will drop and in patients who are hypoxemic at rest at sea level or those who are borderline, the arterial PO_2 may fall to dangerous levels at altitude. Patients whose resting arterial PO_2 at sea level is greater than 70 mm Hg are likely to be safe to fly without supplementary oxygen.^{275,276} When there is uncertainty about a patient's potential oxygen requirement at altitude, an altitude simulation test can be performed, using 16% oxygen to simulate the partial pressure of oxygen at 8000 feet.²⁷⁷

For patients who require in-flight oxygen, arrangements must be made with the airline in advance. In general, patients may not bring their own oxygen supply, and airlines usually charge for the oxygen they provide. Lightweight portable oxygen concentrators have become available in recent years, and these are approved by the FAA for commercial air travel. Some airlines allow passengers to travel with their own concentrators.

Technical Issues for Oxygen Use

Most patients receive oxygen via a nasal cannula. Flow rates should be adjusted to achieve an SpO_2 greater than 90% (arterial $\text{PO}_2 > 60$ mm Hg). In general, patients who use oxygen 24 hours/day should increase the oxygen flow by 1 L/min during sleep and exercise, to prevent falls in arterial PO_2 during these periods. Oxygen conserving devices that improve the efficiency of oxygen delivery increase the time that a given volume of portable oxygen will last, allowing patients greater mobility. These include nasal cannulae with reservoirs that store oxygen during exhalation for delivery during inhalation, as well as breath-activated regulators that deliver an oxygen pulse only during inspiration. For use in the home, electric-powered oxygen concentrators are the most convenient, for they do not require refilling or replacement as is the case with gas cylinders or liquid oxygen. It is important that patients who depend on a concentrator have back up cylinders on hand, in case of a power failure. Ambulatory systems include E-cylinders on wheeled carts, lightweight aluminum cylinders, liquid oxygen reservoirs, and portable concentrators. Many of these ambulatory systems weigh less than 10 pounds and provide oxygen for 4 to 6 hours at a flow of 2 L/min.

PULMONARY REHABILITATION

Pulmonary rehabilitation is a comprehensive program that combines exercise training, smoking cessation, nutrition counseling, and education, in an attempt to improve the functional capacity and quality of life of patients with COPD. Formal rehabilitation programs have been shown to improve exercise capacity and quality of life, and to decrease dyspnea and health care utilization.²⁷⁸⁻²⁸¹ In addition, a recent Cochrane review suggests that pulmonary rehabilitation decreases mortality.²⁸² Pulmonary rehabilitation should be offered to all patients with COPD who are symptomatic (see Chapter 105).

SURGICAL TREATMENT OF EMPHYSEMA

More than 50 years ago, anecdotal reports of symptomatic improvement in patients with emphysema who underwent resection of concomitant lung cancers or bullae led physiologists to consider *lung volume reduction surgery* (LVRS) to improve the mechanical efficiency of respiratory muscles. Because of hyperinflation, respiratory muscles are forced to operate on the disadvantageous part of the length-tension curve; reducing hyperinflation was predicted to improve force generation by respiratory muscles, to improve lung elastic recoil, and to improve expiratory flow rates. Unfortunately, early procedures were associated with an unacceptably high mortality rate. In 1995, Cooper and colleagues²⁸³ reported on their experience with 20 patients who underwent bilateral LVRS. By using a linear stapling device and strips of bovine pericardium to minimize air leak through the staple holes, they were able to eliminate this major cause of early mortality, and reported very impressive improvements in FEV_1 , arterial PO_2 , 6MWD, dyspnea, and quality of life. This was followed by the *National Emphysema Treatment Trial* (NETT), a precedent-setting collaborative effort of the Centers for Medicare and Medicaid Services, the National Heart, Lung, and Blood Institute, and the Agency for Healthcare Research and Quality. NETT enrolled 1218 patients with severe emphysema and compared LVRS to maximal medical treatment.⁴⁶ In patients with upper lobe predominant emphysema and a low post-rehabilitation exercise capacity, LVRS improved survival and quality of life.²⁸⁴ In those patients with FEV_1 less than or equal to 20% predicted and either homogeneous distribution of emphysema or DL_{CO} less than or equal to 20% predicted, mortality was greater with LVRS compared to medical management.²⁸⁵ These criteria are currently used to select patients for LVRS.

In an attempt to minimize risk, several groups have developed techniques for bronchoscopic lung volume reduction. Using a flexible bronchoscope, one-way endobronchial valves are placed in airways that lead to emphysematous areas of the lung. In the presence of intact interlobular fissures (and thus little collateral ventilation), air leaves and cannot reenter these areas, causing them to collapse. As a result, hyperinflation is less, and more ventilation goes to more normal lung.²⁸⁶ The largest prospective trial to date described modest improvements in lung function, 6MWD, and symptoms, but this was associated with more frequent exacerbations of COPD, more pneumonia, and hemoptysis after implantation.²⁸⁶ The role of endobronchial valves for

emphysema remains to be determined, and studies are ongoing to define the best valve design, the best technique, and the most appropriate patient population.

ACUTE EXACERBATIONS

Definition

Perhaps surprisingly, it has not been easy to define an acute exacerbation of COPD. GOLD¹⁷⁵ states, “An exacerbation of COPD is an acute event characterized by a worsening of the patient’s respiratory symptoms that is beyond normal day-to-day variations and leads to a change in medication.”²⁸⁷⁻²⁸⁹ This works sufficiently well that it allows for classification of events in various studies and for comparisons across trials.

Triggers

Exacerbations of COPD are precipitated most often by respiratory tract infections. These may be viral or bacterial. Recent data suggest that a key event, even in individuals whose airways are chronically colonized by bacteria, is the acquisition of bacterial strains that are new to that patient.²⁹⁰ Many patients are sensitive to air pollutants and suffer an exacerbation when ambient levels increase.²⁹¹⁻²⁹³ In perhaps 30% of patients with COPD, no cause for exacerbations can be identified. Interestingly, some patients have an exacerbation whenever one of these events takes place; others rarely do. Those who experience two or more exacerbations per year are often defined as “frequent exacerbators”¹³⁷ and pose a unique challenge for management.

Treatment

The goal of treatment is to minimize the impact of the current exacerbation, to minimize loss of lung function, and to prevent the development of subsequent exacerbations. The vast majority of exacerbations can be managed without hospitalization. Indications for hospitalization include severe dyspnea or respiratory insufficiency, severe underlying COPD, serious comorbidities, frequent exacerbator phenotype, older age, and insufficient support at home. Supplemental oxygen should be administered if necessary, to achieve an SpO₂ greater than 88%. After 30 to 60 minutes, arterial blood gases should be assessed for evidence of carbon dioxide retention.

Bronchodilators. During an acute exacerbation, short-acting β -agonists should be used aggressively, alone or in combination with muscarinic antagonists. Although metered dose inhalers, when used correctly, can be as effective as nebulizers,²⁹⁴ it can be difficult for severely dyspneic patients to coordinate their efforts to use a metered-dose inhaler, or to generate sufficient inspiratory flow required for some devices.

Corticosteroids. Substantial data support the use of systemic corticosteroids for treatment of exacerbations of COPD. Their use is associated with a more rapid recovery, improvement in lung function and hypoxemia, and a reduced risk of relapse.²⁹⁵⁻²⁹⁸ Guidelines recommend 40 to 60 mg prednisone per day for 2 weeks, but a recent prospec-

tive trial of more than 300 patients found that 5 days of prednisone was not inferior to 14 days of prednisone for preventing reexacerbation within 6 months and was associated with a significantly lower total corticosteroid exposure.²⁹⁹

Antibiotics. The use of antibiotics for exacerbations of COPD is somewhat controversial, largely because of the paucity of data documenting bacterial colonization or infection. Studies have suggested that nearly 50% of acute exacerbations are associated with *H. influenzae*, *S. pneumoniae*, and *M. catarrhalis*.³⁰⁰ Even when patients are chronically colonized, changes in strain may be associated with exacerbations.²⁹⁰ Sputum cultures are of limited utility because they do not distinguish between colonization and infection, and because of the time required for results. Most guidelines recommend empirical treatment when infection seems likely, based on what are sometimes called the “Anthonisen criteria”: increased dyspnea, sputum volume, and sputum purulence,³⁰¹ with greater weight given to meeting all three criteria. The recommended length of antibiotic treatment is 5 to 10 days.

DEVELOPMENT OF NEW TREATMENTS

Despite advances in recent years, treatment options for COPD are woefully inadequate. Other than smoking cessation and supplementary oxygen in patients who are hypoxemic, there are no treatments that reduce mortality. Several factors have contributed to the lack of progress. COPD is highly heterogeneous: in some patients, emphysema predominates; in others, bronchitis predominates. Still others may have both. COPD is a systemic disease and, as a consequence, comorbid extrapulmonary conditions are common. Because treatment effects are small, very large studies are required to test potential new interventions. For all of these reasons, investigators are beginning to explore individual patient subtypes, looking for subpopulations that might benefit from unique therapeutic regimens, and for intermediate outcomes measures that might increase the efficiency of clinical trials. To this end, the National Heart, Lung, and Blood Institute has funded the Subpopulations and Intermediate Outcomes in COPD Study (SPIROMICS),³⁰² a prospective observational study of COPD subjects and controls. Complementary studies such as Evaluation of COPD Longitudinally to Identify Predictive Surrogate Endpoints (ECLIPSE)³⁰³ and COPDGene³⁰⁴ will hopefully add to the explosion of knowledge in the next few years, aimed at improving treatment for patients with COPD.

Key Points

- Chronic obstructive pulmonary disease (COPD) is a highly prevalent disease and a leading cause of mortality. COPD is significantly underdiagnosed.
- COPD is characterized by airflow obstruction that is not fully reversible. Spirometry is required for diagnosis.
- Older age and a history of smoking are the two most important risk factors for COPD.

- Emphysema at a young age or in an individual with minimal or no smoking history should suggest α_1 -antitrypsin deficiency.
- Smoking cessation is the only intervention demonstrated to alter the course of lung function decline. Smoking cessation also conveys a long-term mortality benefit.
- Pharmacotherapy is no longer for symptom relief only. Short- and long-acting muscarinic antagonists, long-acting β -agonists, and inhaled corticosteroids have been shown to improve exercise capacity, improve quality of life, and reduce exacerbations.
- Choice of medications is based in part on the availability of medication and the patient's response. The Global Initiative for COPD has proposed a stepwise treatment algorithm, based on a combination of airflow obstruction (spirometry), symptoms, and risk of future exacerbations.
- In patients with hypoxemia, continuous oxygen treatment for at least 15 hours/day improves survival, quality of life, and a number of other measures.
- Patients with arterial PO_2 less than 55 mm Hg or SpO_2 less than 88% while breathing room air at rest, or patients with arterial PO_2 56–59 mm Hg and erythrocytosis or cor pulmonale, should be offered continuous oxygen treatment.
- Pulmonary rehabilitation improves exercise capacity and quality of life, and decreases dyspnea and health care utilization, as well as hospitalizations and mortality. Pulmonary rehabilitation should be offered to any patient in whom shortness of breath develops while walking.
- Lung volume reduction surgery may be beneficial for the small subgroup of patients with upper lobe-predominant emphysema and a low post-rehabilitation exercise capacity.

GENETICS OF ASTHMA AND COPD: LESSONS LEARNED AFTER 20 YEARS OF EXPERIENCE**INTRODUCTION**

Asthma and *chronic obstructive pulmonary disease* (COPD) are chronic inflammatory airway diseases that result from an interaction between genetic or host susceptibility and different environmental exposures. Both airway diseases are common with an estimated 300 million individuals with asthma and 64 million individuals with COPD worldwide.^{1,2} Genetic variation has major effects on asthma and COPD susceptibility; however, these are not isolated to a single gene, but represent the effects of many different genes that are polymorphic (contain gene variants or polymorphisms) or undergo epigenetic regulation (changes in gene expression without changes in the genetic code, i.e., gene methylation), causing disease risk or severity (Fig. 45-1). Thus, in contrast to *single gene disorders* such as cystic fibrosis, asthma and COPD are caused by the effects of multiple genes with smaller effects and genetically are referred to as *complex genetic disorders*. Recent genetic studies suggest that there may be common genetic variants that influence the susceptibility and severity of both of these “complex”

obstructive airway diseases. Multiple potential environmental exposures interact with risk or severity genes for the development or progression of asthma, while cigarette smoke exposure is the primary environmental factor for the development of COPD.

Information from genetic studies has advanced remarkably since the sequencing of the first genome in 2001 and the completion of the International HapMap project in 2005. Based on initial studies in families, it is clear that susceptibility to asthma and COPD is determined by multiple genetic loci in different genes.³ Since then, high-throughput genotyping techniques using chip technologies for *genome-wide association studies* (GWAS) have facilitated comprehensive assessment of gene variation in a larger number of subjects and, more recently, sequencing of the whole genome or of all of the exomes. In contrast to asthma, which may be recognized as early as infancy, COPD presents at a later age; therefore, family-based studies are not practical or feasible. Thus, candidate gene association and GWAS have been used to investigate the genetic basis of COPD. The exponential growth of the field of asthma and COPD

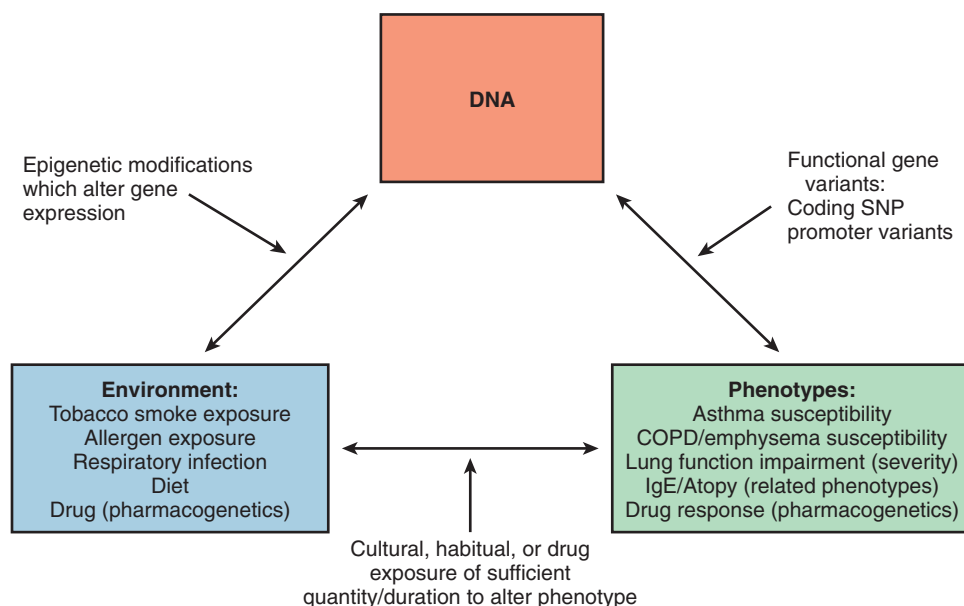

Figure 45-1 Premise of genetic research in complex diseases. Genetic research studies the role of genetic variability in determining risk for complex airway diseases, related phenotypes, and disease severity. Genetic risk can be altered by gene variants that directly impact biologic function or act through gene-by-environment interactions that alter gene function or expression through epigenetic mechanisms. Pharmacogenetics research studies a similar gene-by-environment interaction by analyzing the effect of genotype and exposure to a medication in determining interindividual responses to pharmacologic therapies. IgE, immunoglobulin E; SNP, single nucleotide polymorphism.

genetics in the past decade has dramatically shortened the time from identification of phenotype to discovery of the gene variant in these complex airway diseases.

Different genetic studies have focused on disease susceptibility, disease severity, and therapeutic responses (i.e., pharmacogenetics). These genetic approaches require large, well-characterized populations. Unfortunately, because of the large population samples required for GWAS, the emphasis on comprehensive phenotyping has not been given priority and the results of these resource-intensive genetic studies have not always provided adequate information on subpopulations and disease heterogeneity. Overall, genomic approaches will provide a basis for the development of personalized medical strategies where molecular profiles based on variation in multiple genes or gene pathways will be used to develop a predictive genetic disease or severity score.⁴⁻⁶ Such a score could be used to predict which individuals are at risk for asthma or COPD and would facilitate the development of strategies to prevent disease development or progression.⁷ In those who already have these diseases, genetic profiles would provide a molecular rationale for disease heterogeneity, progression, and the basis for variable responses to therapeutic agents.^{8,9} These genetic profiles should facilitate precise, personalized, and patient-focused therapeutic approaches with the potential to target disease progression, maximize therapeutic efficacy, and minimize unwanted side effects or negative responses.^{7,10,11}

This chapter outlines how human genetic studies in asthma and COPD have identified gene targets, which has substantially improved understanding of the molecular basis of the development, progression, and pharmacogenetics in asthma and COPD. These genetic approaches have the potential to contribute to the development of precision or personalized medicine in obstructive airway disease.⁴ These same genetic approaches have been used in other

complex diseases (e.g., cardiovascular, metabolic, cancer) to identify genetic determinants of disease susceptibility and progression.¹²

EARLY GENETIC STUDIES OF ASTHMA SUSCEPTIBILITY: FAMILY-BASED GENETIC STUDIES

EVIDENCE THAT ASTHMA IS HERITABLE

A genetic basis for asthma was recognized as early as 1860 when Henry Salter reported that asthma was a heritable disease with “distinct traces of inheritance” among related individuals.¹³ Salter’s observation was confirmed in studies demonstrating that asthma prevalence was between 20% and 25% among first-degree relatives of asthma subjects, significantly higher than the approximately 5% prevalence in the general population.^{14,15} The clustering of asthma in families is estimated by comparing the risk for developing asthma in those related to an asthmatic proband with the risk for asthma in the general population as a *lambda ratio* (λ_R). A higher λ_R indicates that the disease has greater heritability and, therefore, a stronger genetic component. For instance, asthma has a λ_R of 2 to 4 while an autosomal recessive disease such as cystic fibrosis has a much higher λ_R . The lower λ_R of a common, complex disease such as asthma is likely caused by multiple gene variants each with small effects interacting with factors not detected in heritability studies, including a diverse group of environmental exposures and disease triggers. The observed heritability for asthma demonstrated in these early studies provided the rationale for the comprehensive genetic studies discussed in this chapter.

THE FIRST GENOME-WIDE SCREENS FOR SUSCEPTIBILITY LOCI: FAMILY-BASED STUDIES

The first genetic studies for asthma susceptibility, which were performed before the first genomes were sequenced, used family-based approaches.^{3,16-26} They used genetic variants that are equally spaced throughout the genome to identify chromosomal susceptibility regions for asthma or associated phenotypes (e.g., bronchial hyperresponsiveness, serum IgE levels, skin test atopy). In family-based genetic studies, linkage analysis is used to identify genetic loci that cosegregate or are coinherited with a trait such as asthma in families. The degree of linkage is measured as an LOD score, the “likelihood of the odds” that a genomic region and trait cosegregate (Table 45-1). An LOD score of 3 or more is considered significant and is equal to a 1000:1 odds that a genomic region is in linkage or coinherited with a specific trait or phenotype. Family-based studies have been successful in identifying genetic diseases with an autosomal dominant or recessive mode of inheritance, but are less powerful for complex or multifactorial diseases wherein

multiple genes interact to determine disease susceptibility or severity. Transmission disequilibrium testing is another family-based association test that compares the transmission of a genetic marker from both parents to their affected offspring with a disease or trait of interest (see Table 45-1 and Fig. 45-2).²⁷

Early family-based genome-wide studies demonstrated that multiple genes are associated with development of asthma and of related phenotypes such as atopy and elevated serum *immunoglobulin E* (IgE). These studies, including those performed by the *National Heart, Lung, and Blood Institute (NHLBI) Collaborative Study on the Genetics of Asthma* (CSGA), provided evidence for linkage with asthma and related phenotypes in multiple different chromosomal regions: chromosome 5q, 6p, 7q, 11q, 12q, 14q, and 16q.^{3,24,26,28-40} The genetic markers identified by these family-based studies represent chromosomal regions that have subsequently been studied to identify specific risk genes responsible for these linkages (eTable 45-1).

These early linkage studies demonstrated gene-gene interactions in asthma susceptibility between chromosomes

Table 45-1 Different Methodologies* for Genetic Studies			
Methodologies	Population	Genome Coverage	Test Measurement
Family, twin, or segregation study	Families	None	Clustering in families to estimate heritability
Linkage study	Families (pedigrees)	Genome-wide	Cosegregation of a marker and phenotype with the likelihood of the odds score
Family-based association test	Small families (trios)	Gene to genome-wide	Transmission of a marker from parents to cases-controls with transmission disequilibrium testing
Candidate gene association study	Cases and controls	Gene	Odds ratio or genetic risk and <i>P</i> -value
Genome-wide association study	Cases and controls	Genome-wide	Odds ratio or genetic risk and <i>P</i> -value
Admixture mapping	Cases and controls	Gene to Genome-wide	Admixture mapping association peak and <i>P</i> -value

*Methodologies are described by the target population analyzed, coverage ranging from the individual gene-level to genome-wide level resolution, and the analytical test measured.

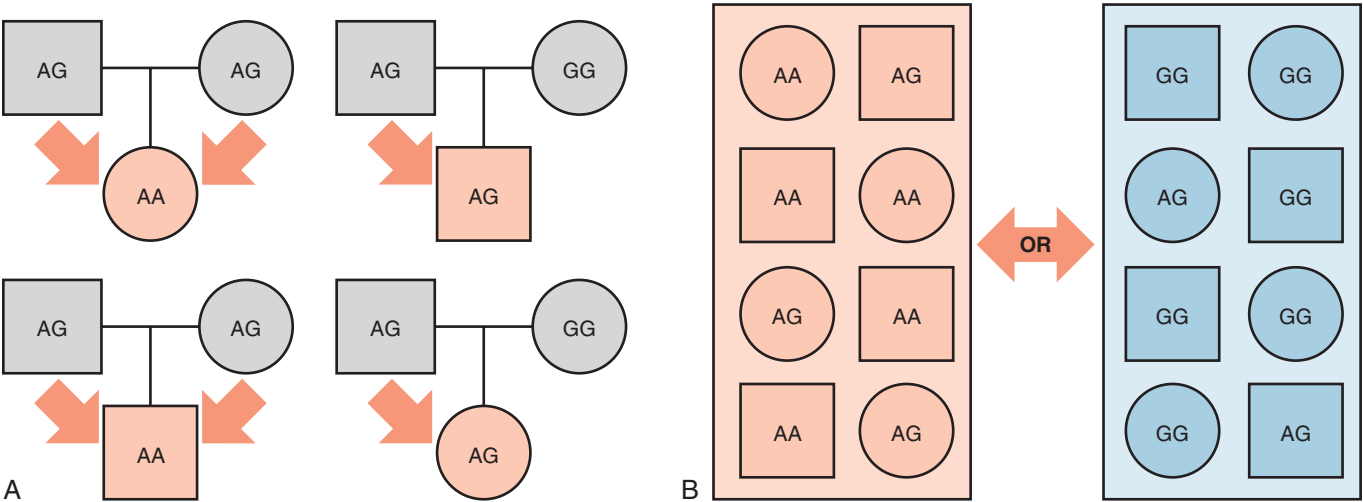

Figure 45-2 Two commonly used association testing methods: family-based and case-control. **A**, Family-based association testing. The basic fundamental unit of family-based association testing are the trios of affected (cases in red) probands. Trios consist of cases or affected probands and their parents, whose affected status is not necessarily known (in gray). In family-based studies, the over transmission of an allele of a polymorphism to affected probands is measured (red arrows). This demonstrates how a single nucleotide polymorphism (SNP) with alleles “A” or “G” shows overtransmission of the “A” allele to affected probands. The strength of the overtransmission or association at this locus is estimated using the *P*-value. **B**, Case-control association testing. Case-control association testing compares the frequency of the different alleles for this SNP in unrelated cases (in red) and controls (in blue) to determine an odds ratio (OR, red double-arrow) or genetic effect. The basic illustration demonstrates that the “A” allele is more frequent among cases compared to controls. The strength of the association at this locus is estimated using the *P*-value.

eTable 45-1 Candidate Genes for Susceptibility to Asthma and Related Phenotypes in Chromosomal Regions Identified through Linkage Studies*

Gene Names	Chr Pos	Gene ID	Associated Phenotypes	References
A Disintegrin And Metalloprotease-33	20p13	<i>ADAM33</i>	Asthma, bronchial responsiveness, lung function, lung function rate decline	21, 50–52
β-chain of the high-affinity receptor for IgE	11q13	<i>FCER1B</i>	Asthma, IgE, skin test atopy	3, 35–37, 71, 75
Dipeptidyl Peptidase-10	2q14	<i>DPP10</i>	Asthma, IgE, skin test atopy	3, 58, 59, 114, 115
Interleukin-4	5q31	<i>IL4</i>	Asthma, IgE, skin test atopy, lung function	25, 31, 33, 83–89, 98
α-chain of the Interleukin-4 Receptor	5q31	<i>IL4R</i>	Asthma, IgE, skin test atopy, lung function	25, 31, 33, 95, 96, 98–100
Interleukin-13	5q31	<i>IL13</i>	Asthma, bronchial responsiveness, IgE, skin test atopy	25, 31, 33, 72, 79–82, 98
CD14	5q31	<i>CD14</i>	Asthma	25, 31, 33, 76, 77
Protocadherin-1	5q31	<i>PCDH1</i>	Bronchial responsiveness	25, 31, 33
Tumor Necrosis Factor-α	6p21	<i>TNF</i>	Asthma, bronchial responsiveness, IgE, skin test atopy	3, 24, 40, 64, 66–70, 114
Human Leukocyte Antigen Complex DPB1	6p21	<i>HLA-DPB1</i>	Asthma	3, 24, 40, 74, 114
Human Leukocyte Antigen Complex DQB1	6p21	<i>HLA-DQB1</i>	Asthma	3, 24, 40, 72, 73, 114
Human Leukocyte Antigen Complex DRB1	6p21	<i>HLA-DRB1</i>	Asthma, skin test atopy	3, 20, 24, 40, 114, 145
Human Leukocyte Antigen Complex G	6p22	<i>HLA-G</i>	Asthma, bronchial responsiveness	3, 24, 40, 63, 114
Neuropeptide S Receptor-1 (NPSR1)	7p14	<i>GPRA</i>	Asthma, IgE	38, 63a
PHD Finger Protein-11	13q14	<i>PHF11</i>	Asthma, IgE	3, 61

*Candidate genes listed are within linkage regions from family-based studies or replicated in case-control association studies. Genes are summarized by full gene name, chromosomal position (Chr Pos), gene identification (ID) acronym, associated asthma or related phenotype, and references cited.

5q31, 8p23, and 12q22, and 15q13.²² In addition, these studies provided evidence for gene-by-environment interactions between passive cigarette smoking and asthma susceptibility at chromosomes 1p, 5q, and 9q, and 17q21.^{17,41-43} These gene-by-environment interactions provided the earliest examples of important epigenetic effects in asthma in which environmentally induced DNA modifications alter transcription without a change in gene sequence.

Early family-based linkage studies also provided evidence for genetic determinants of altered pulmonary function in asthma. In these studies, a quantitative trait locus on chromosome 5q33 and 2q32 was linked with important lung function measures.^{18,44-46} The quantitative trait locus in chromosome 2q32 was adjacent to the region linked to *forced expiratory volume in 1 second/forced vital capacity* (FEV₁/FVC) in families with early-onset COPD suggesting that there may be similar genes that affect the development of both asthma and COPD.⁴⁷

LINKAGE STUDIES PROVIDE IMPORTANT INSIGHT INTO THE COMPLEXITY OF ASTHMA PATHOGENESIS

The limitations of family-based linkage studies include the challenge of recruiting and characterizing related subjects and the use of genetic markers that cover genomic regions that contain hundreds of genes, requiring more detailed analysis with fine mapping or positional cloning to identify individual susceptibility genes. Another important limitation of family-based linkage studies is that they were designed to identify loci containing gene variants with a strong effect on disease susceptibility and are underpowered to detect common gene variation with a weak or modest effect. Despite these limitations, novel asthma genes have been identified (see eTable 45-1) which provide insight into the polygenic pathogenesis and the importance of gene-environment interactions in asthma.

LINKAGE ANALYSIS AND POSITIONAL CLONING REVEAL NOVEL ASTHMA SUSCEPTIBILITY LOCI

A *disintegrin and metalloprotease-33 gene* (*ADAM33*) was the first gene identified for asthma susceptibility using a family-based linkage study followed by fine mapping and association studies with cases and controls (i.e., positional cloning). It was identified by positional cloning on chromosome 20p13.²¹ *ADAM33* encodes for a membrane-anchored glycoprotein that controls cell-matrix interactions and is involved in regulation of lung growth and morphogenesis.^{48,49} The *ADAM33* protein is expressed in airway smooth muscle cells and lung fibroblasts, contains a catalytic domain with proteolytic activity and affects airway remodeling. *ADAM33* is among the most replicated genes for asthma susceptibility in different racial and ethnic groups.⁵⁰⁻⁵³ *ADAM33* gene variants have been associated with accelerated decline in lung function in asthma and in COPD, suggesting a role of this gene in the pathogenesis of progressive airflow obstruction.⁵⁴⁻⁵⁶ This is further supported by the observation that bronchoalveolar lavage concentrations of soluble *ADAM33* correlate with asthma severity and inversely correlate with lung function.⁵⁷

Other family-based whole-genome studies used positional cloning to identify the *dipeptidyl peptidase-10* (*DPP10*) gene on chromosome 2q14 as a locus for asthma susceptibility.⁵⁸ A *single nucleotide polymorphism* (SNP) in *DPP10* was recently identified in a GWAS of African Americans and African Caribbeans, providing additional evidence that *DPP10* is an asthma susceptibility locus.⁵⁹ Dipeptidyl peptidases cleave the terminal peptides of cytokines and chemokines and enhance airway inflammation. Several other asthma susceptibility genes have been identified using fine mapping or positional cloning techniques and include the *protocadherin-1* gene (*PCDH1*) on chromosome 5q31, *human leukocyte antigen complex G* (HLA-G) on chromosome 6p22, the *neuropeptide S receptor-1* gene (*GPRA*) on chromosome 7p14, and *PHD finger protein-11* (*PHF11*) on chromosome 13q14 (see eTable 45-1).^{3,38,60-63,63a} The identification of asthma susceptibility loci is an example of the use of *unbiased* genetic techniques, that is, without preconceived notions of mechanism, to delineate novel biologic mechanisms that are important in the pathogenesis of asthma.

CANDIDATE GENE ASSOCIATION STUDIES IN ASTHMA

As high-throughput genotyping technologies emerged that facilitated genotyping in larger populations, a greater number of biologic candidate genes were investigated in unrelated asthma case and control populations. In contrast to family-based approaches, case-control association studies compare the frequency of the alleles of a gene variant between unrelated cases and controls (see Fig. 45-2). Association analysis is a very useful approach for common diseases wherein alleles confer a small disease risk. SNPs (i.e., point mutations) represent the substitution of a single nucleotide for another, resulting in variable frequencies of the variant allele in a sample population. SNPs are denoted as a *reference sequence* (rs) number or by the coding change at a specific codon position number for nonsynonymous SNPs (e.g., rs1042713 or Gly¹⁶Arg) and represent the primary gene variants used in association studies. (*Nonsynonymous* refers to a change in sequence that alters the amino acid sequence of a protein; *synonymous*, on the other hand, is a change in sequence that does not alter the protein.)

More than 100 genes have been studied as biologic candidate genes based on plausible biologic mechanisms in asthma or locations in chromosomal regions linked to asthma (see eTable 45-1).^{21,58} For each replicated candidate gene for asthma susceptibility that has been discovered, there are studies that may not show an association, perhaps because of differences in phenotypes or differences in race between populations (see later). The most replicated candidate genes appear to be related to broad categories of lung development (e.g., *ADAM33*), the *type 2 T helper cell* (Th2) inflammatory pathway (*IL4*, *IL13*, *IL4R*), innate immunity (*HLA-DRB1*, *HLA-DQB1*, *CD14*), and cellular inflammation (*TNF*, *FCER1B*, *DPP10*) (see eTable 45-1).^{3,21,58,59,63-75} In addition, candidate genes within the glucocorticoid receptor complex pathway, the leukotriene pathway (*LTC4S*), the

β_2 -adrenergic receptor gene (*ADRB2*), and the Th2 inflammatory pathway signaling (*IL4R*) have also been evaluated as potential pharmacogenetic loci that modify responses to pharmacologic therapy.⁷⁶⁻⁹⁴

HIGHLY REPLICATED CANDIDATE GENES ON CHROMOSOME 5q31 AND EVIDENCE FOR GENE-GENE INTERACTIONS

Linkage analyses of chromosome 5q31-35 have consistently provided evidence that this region is linked to asthma or closely related phenotypes.^{25,31,33,62} This inflammatory gene-rich region contains multiple candidate genes related to allergic inflammation, including *IL3*, *IL4*, *IL5*, *IL13*, *CD14*, *serine peptidase inhibitor Kazal type 5* (*SPINK5*), the β_2 -adrenergic receptor (*ADRB2*), and *leukotriene C4 synthase* (*LTC4S*). The gene encoding for *IL-13* and *IL-4* contains promoter SNPs and variants consistently associated with asthma and related phenotypes in multiple populations.^{79,80,84,86-88} *IL-13* and *IL-4* bind to the α chain of the *IL-4* receptor encoded by *IL4R* on chromosome 16p12, which also contains variants associated with asthma and related phenotypes.^{95,96} The interaction of two variants in *IL4R* has been associated with risk for life-threatening asthma exacerbations in persistent asthmatics suggesting a role of this pathway in determining disease severity.⁹⁷ In addition, interactions between genetic variants in *IL4*, *IL13*, and *IL4R* and other pathway-related genes such as *STAT6* on chromosome 12q13 cumulatively determine asthma risk and serum IgE at a greater level than does each individual locus, supporting the role of multiple genes interacting in asthma susceptibility and pathogenesis.⁹⁸⁻¹⁰⁰ Finally, one of the first GWAS in a population of severe or difficult-to-treat asthmatics demonstrated SNPs in *IL13* and a neighboring gene encoding for a DNA repair protein (*RAD50*) as a locus for asthma susceptibility.⁷² The interaction of variants in different Th2 inflammatory pathway signaling genes has been critical to understanding the nature of gene-gene interactions in determining asthma susceptibility and severity. Furthermore, these positive associations for the *IL-4*–*IL-13* pathways have supported the current development of biologic therapies targeting these cytokines.^{93,101,102}

LIMITATIONS OF CANDIDATE GENE ASSOCIATION STUDIES: LESSONS LEARNED AND THE ROAD TO GWAS

All association studies, including candidate gene studies, are limited by the need to ascertain well-characterized case-control populations.^{103,104} An issue with early association studies was the small sample sizes (<200 cases) resulting in studies underpowered to identify gene variants with small effects and prone to false-positive results. Unrelated cases and controls have variable ancestral backgrounds, which may lead to false-positive results. SNP allele frequencies vary in different populations based on ancestry (population stratification), which may cause spurious differences in allele frequencies between cases and controls if different ethnic groups are analyzed (i.e., false positives).

The need to account for potential population stratification in genetic association studies is true for all types of

association studies but was well recognized and implemented in candidate gene studies. Another limitation of all association studies is the underlying correlation of alleles in genetic loci located in a chromosomal region (i.e., *linkage disequilibrium* or LD). For example, if two genetic loci are physically close together, they will be inherited as one unit through multiple generations. In this case, an association study would result in positive results for both genes, making it difficult to isolate the gene or variant of interest. This is especially true for SNPs within a gene. However, in older populations of more generations or admixed population, there have been more opportunities to break the correlation, thus allowing the true risk allele or loci to be identified.

GENOME-WIDE ASSOCIATION STUDIES FOR ASTHMA SUSCEPTIBILITY

In GWAS, large numbers of SNPs are genotyped using chip technologies that cover the genome, usually with 500,000 to more than 1 million SNP genotypes (SNP variants) assessed in large case and control populations. Earlier chips contained fewer SNPs and did not provide good coverage of the genome in all races that show differences in allele frequencies based on ancestry. The overall limitation is the degree of phenotyping that can be performed in these large samples (see Fig. 45-2). In GWAS, the frequencies of the alleles of each SNP are compared between unrelated cases and controls on a genome-wide scale (see Fig. 45-2).

SNPs are the most common form of gene variation and are seen in 1 of every 100 nucleotides in the human genome; therefore, SNPs used for GWAS provide comprehensive coverage of each gene and the entire genome. The ability to genotype a larger number of SNPs rapidly and simultaneously has enabled GWAS approaches to identify a number of novel loci associated with asthma susceptibility, related phenotypes, and disease severity. In addition, whole-genome genotyping provides information about population substructure, an index of ancestral admixture. All GWAS studies discussed later have adjusted associations by population substructure to minimize confounding by population stratification (eTable 45-2). A small number of studies have used genome-wide family-based association studies (i.e., transmission disequilibrium test) to minimize this source of confounding by population stratification (see Fig. 45-2).²⁷ GWAS requires a more stringent *P*-value due to multiple testing of a large number of SNPs, and subsequent replication testing of significant SNP associations in independent samples is important.

GWAS IDENTIFIES *ORMDL3* AS A SUSCEPTIBILITY LOCUS

In 2007, a GWAS for asthma susceptibility was performed in a European cohort (GABRIEL). SNPs in the *ORM1-like 3 gene* (*ORMDL3*) region on chromosome 17q12 were significantly associated with the diagnosis of childhood asthma and this finding was replicated in two independent cohorts.¹⁶ A second larger GWAS by the European GABRIEL

eTable 45-2 Major Susceptibility Loci for Asthma Identified through GWAS*

Gene Names	Chr Pos	Gene ID	Racial or Ethnic Populations	Initial Reported Locus	References
ORM1-Like 3	17q12	<i>ORMDL3</i>	European, European American, African American, African Caribbean, Hispanic, Chinese	rs7216389	16, 73, 105–110

*Susceptibility loci for asthma identified through genome-wide association studies summarized by full gene name, chromosomal position (Chr Pos), gene identification (ID) acronym, racial or ethnic groups where associations were observed, initial locus (by single nucleotide polymorphism rs number) reported to be associated with asthma through GWAS, and references cited.

consortium validated *ORMDL3* as a locus for asthma risk while identifying additional susceptibility loci in the neighboring gasdermin-like genes (*GSDMB* and *GSDMA*) as well as other loci in the genome, including *IL1RL1/IL18RL1* (between the *IL1* and *IL18* receptor genes, rs3771166) on chromosome 2q12, *HLA-DQB1* (rs9273349), *IL33* on chromosome 9p24 (rs1342326), *SMAD3* on chromosome 15q22 (rs744910), and *IL2RB* on chromosome 22q12 (rs2284033).⁷³

Gene variants in the *ORMDL3* locus have been associated with asthma in multiple subsequent GWAS, making *ORMDL3* the most replicated locus using genome-wide screening methods in case-control populations.¹⁰⁵⁻¹¹⁰ The challenge of interpreting genetic associations in chromosome 17q12 is the strong *linkage disequilibrium* (LD) that exists between the variants in multiple genes that span this region. It remains unclear whether the causative gene is *ORMDL3* or an adjacent gene, such as *GSDMB* or *GSDMA*.^{111,112}

This novel asthma susceptibility gene (*ORMDL3*) is a member of a class of genes that encodes transmembrane proteins anchored in the endoplasmic reticulum; however, its specific biologic role in asthma pathogenesis remains unknown. GWAS in asthma have demonstrated a predilection for genes that regulate relevant molecular pathways and are related to epithelial damage and adaptive immune response. It is likely that altered production of cytokines such as *thymic stromal lymphopoietin* (TSLP) and IL-33 from damaged or disrupted epithelial cells promotes Th2-mediated inflammatory responses by activating IL1RL1 receptors on mast cells, Th2 lymphocytes, and regulatory T cells.

GWAS IN AFRICAN AMERICANS AND OTHER ASTHMA POPULATIONS

Subsequent GWAS were performed in multiethnic populations including non-Hispanic white and African American subjects to understand the genetic diversity of populations from different ancestral backgrounds (i.e., ethnic groups) as well as to address the genetic causes of differences in the frequency and severity of asthma in different ethnicities. This is particularly important for ethnic groups such as African Americans and Puerto Ricans who have a greater asthma incidence associated with higher asthma-related morbidity and mortality. These groups may have unique genetic loci due to a higher frequency of risk alleles that determine disease susceptibility or severity.¹¹³ For example, African Americans are at low risk for cystic fibrosis because of the low frequency of *CFTR* mutations in this ancestral population while at higher risk for sickle cell disease due to increased frequency of mutations in that gene.

The EVE consortium combined 5416 asthma cases in a large, multiethnic population representing Americans of European descent, African Americans, African Caribbean, and Hispanics (Mexican Americans and Puerto Ricans) with replication in 12,649 subjects. This large-scale multiethnic GWAS for asthma susceptibility identified genome-wide significant associations with SNPs on chromosome 17q12 (spanning *IKZF3/ZPBP2/GSDMB/ORMDL3*), *IL1RL1*, and *TSLP* on chromosome 5q22. Associations at these loci and a SNP in *IL33* were replicated in indepen-

dent cohorts.¹⁰⁹ This GWAS validated the susceptibility loci identified on the chromosome 17q12 locus and *IL1RL1* confirming their importance in asthma risk (see eTable 45-2).^{16,73}

The EVE consortium also identified SNPs in the pyrin and HIN domain family member 1 (*IFIX*, interferon inducible nuclear protein X gene, *PYHIN1*) associated with asthma in African American and African Caribbean cohorts.¹⁰⁹ The first GWAS of a population from a primarily African ancestry also identified novel susceptibility loci in the α_{1B} -adrenergic receptor on chromosome 5q33 (*ADRA1B*) and prion-related protein on chromosome 20p12 (*PRNP*). In addition, the *DPP10* locus was associated with asthma, confirming earlier positional cloning studies.^{3,58,59,114,115}

GWAS in Asian populations confirm the importance of previously described asthma susceptibility loci in *HLA-DQ*, *HLA-DPA1*, *HLA-DPB1*, and *TSLP* in Japanese and Korean populations.^{74,109,116,117} In addition, five polymorphisms in chromosome 17q12 encompassing *ORMDL3*, *GSDMB*, *ZPBP2*, and *IKZF3* were associated with asthma in a Han Chinese population (see eTable 45-2).¹⁰⁸

ADMIXTURE MAPPING AS AN ALTERNATIVE APPROACH IN ADMIXED POPULATIONS

The colonization of the Americas by the Europeans and the subsequent African slave trade has resulted in the mixing of genetic ancestries and the complex population structures encountered in the genomes of African Americans, African Caribbean, Mexican Americans, and Puerto Ricans. There is marked variability in the demographic histories of these admixed populations of African origin, resulting in a complex population structure and reduced LD that is not fully captured with GWAS that use genotyping platforms designed for non-Hispanic white populations. The recent mixing of these ancestries provides the rationale for genome-wide ancestry-based approaches. African Americans, on average, have an estimated 20% European ancestry (80% African) while Hispanic ethnic groups such as Puerto Ricans and Mexican Americans have a combination of three different ancestries.¹¹⁸⁻¹²⁰

Mapping by admixture linkage (admixture mapping, Fig. 45-3) is a genome-wide approach that is based on the principle that many SNPs show marked variable allele frequencies between different ancestral populations. In admixture mapping, estimates of ancestry at each SNP are tested for association with a phenotype, in contrast to GWAS which compares allele frequencies. Admixture mapping requires a substantially smaller number of genetic markers compared to GWAS and can evaluate regions with rare variants (Fig. 45-4) and other variants such as polynucleotide insertion-deletions. The optimal setting for the use of admixture mapping is in admixed populations where there are marked racial disparities in disease phenotype not attributed completely to environmental factors.^{113,121-123}

Studies of African ancestry in African Americans from the general population have suggested a role for gene variation related to African ancestry on lung function and asthma severity. Estimates of African ancestry are inversely associated with baseline lung function measures in three independent African American populations and Puerto Ricans.^{120,123a} In African Americans, each percentage of

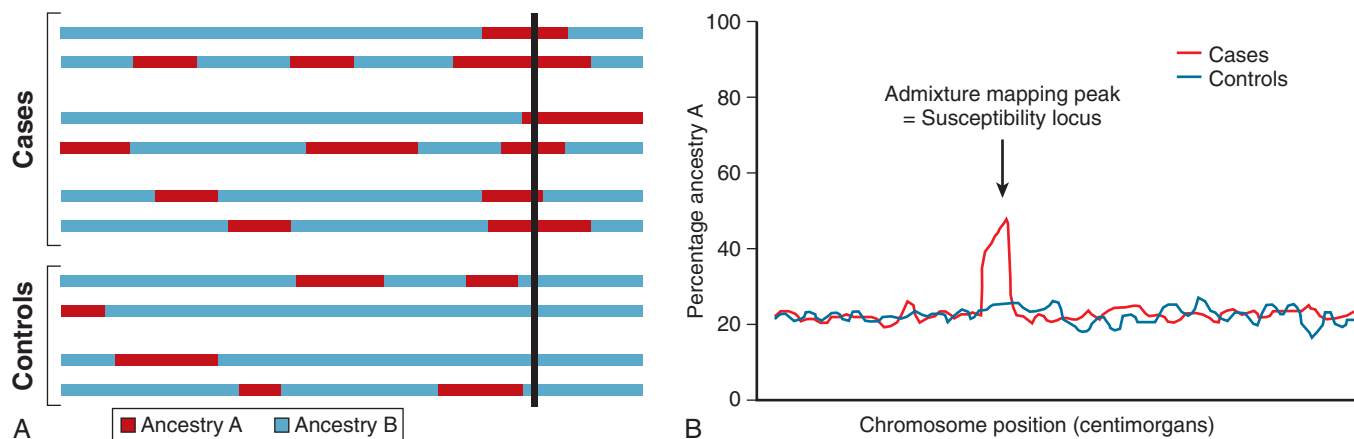

Figure 45-3 Illustration of admixture mapping. **A**, The hypothesis behind mapping by admixture linkage disequilibrium or admixture mapping is that chromosomes from an admixed population (shown with red and blue genetic regions from different ancestries) contain a susceptibility allele that is more frequent in the red ancestral region versus the blue. Admixture mapping identifies increased ancestry at a susceptibility locus in cases compared to controls (region intersected by thick black line). **B**, Loci with significant associations between ancestry and disease risk are represented by admixture mapping peaks or chromosomal regions with an overrepresentation of ancestry from the ancestral population with the highest proportion of risk alleles at the locus containing the risk-invoking variant. (**A**, Adapted from Montana G, Pritchard JK: Statistical tests for admixture mapping with case-control and cases-only data. *Am J Hum Genet* 75:771–789, 2004. **B**, From Patterson N, Hattangadi N, Lane B, et al: Methods for high-density admixture mapping of disease genes. *Am J Hum Genet* 74:979–1000, 2004, Fig. 1.)

Figure 45-4 Impact of genetic variants in human disease. The “common disease–common allele” hypothesis states that multiple common genetic variants with small to modest effect sizes contribute to common disease susceptibility in an additive fashion. Genome-wide association studies (GWAS) have identified multiple common variants associated with risk for different common diseases. In contrast, the “common disease–rare allele” hypothesis states that rare genetic variants with a large effect size contribute to susceptibility for common diseases. Rare variants can only be evaluated with family-based genetic studies, DNA sequencing, and admixture mapping, and are not easily evaluated with GWAS. (Adapted from Tsuji S: Genetics of neurodegenerative diseases: insights from high-throughput resequencing. *Hum Mol Genet* 19:R65–70, 2010.)

African ancestry was associated with a 3 to 5 mL lower FEV₁. This finding has implications for calculating predicted normal lung function in admixed ethnic groups. For example, an African American with 50% African Ancestry is likely to have an FEV₁ up to 200 mL higher compared to an African American of the same age, sex, and height with 90% African ancestry. Estimates of African ancestry have also been associated with risk for self-reported asthma and

asthma exacerbations in African Americans from the United States.^{124,125}

Genome-wide admixture mapping studies have the potential to identify the genetic loci that account for the increased asthma incidence in those with significant African ancestry. Admixture mapping for susceptibility loci has been performed in Puerto Ricans and Mexican Americans from the *Genetics of Asthma in Latino Americans* (GALA)

cohort, and SNPs in nearly 62 loci associated with asthma (i.e., admixture mapping peaks, see Fig. 45-3) have been identified.^{126,127} Admixture mapping in African American and Puerto Rican asthma subjects from the NHLBI-sponsored *Severe Asthma Research Program* (SARP), CSGA, and GALA cohorts has also identified a novel asthma susceptibility locus on chromosome 6q14.1.¹²⁸

GWAS AND ASSOCIATION STUDIES OF SEVERE ASTHMA

Initially, GWAS in asthma were designed to detect susceptibility loci, because detailed phenotyping is time intensive and costly, resulting in small case-control cohorts. Larger populations of comprehensively characterized cohorts were recruited for the NHLBI-sponsored SARP and the TENOR (The Epidemiology and Natural History of Asthma: Outcomes and Treatment Regimens) Study. A GWAS of severe asthmatics from TENOR identified multiple loci associated with asthma: rs2244012 in *RAD50* adjacent to *IL13*, rs1063355 in *HLA-DQB1*, and rs3998159 between *HLA-DQB1* and *HLA-DQA2*. These findings confirm the importance of Th2 cytokine and antigen presentation genes in asthma pathogenesis and potentially in asthma severity.^{3,24,40,72,79,80,114,129} Associations at these loci have also provided evidence for a common immunogenic pathway between asthma and autoimmune disease. For example, the *IL13* asthma locus is also associated with psoriasis.¹³⁰ A recent GWAS of children between 2 and 6 years of age from the Copenhagen Prospective Studies on Asthma in Childhood Exacerbation cohort with recurrent, severe exacerbations identified four previously identified susceptibility loci in *GSDMB*, *IL33*, *RAD50*, and *IL1RL1* as associated with risk for this severe asthma phenotype.^{16,73,109,131} In addition, this GWAS identified a novel locus for severe childhood asthma on the gene encoding *cadherin-related family member-3* (*CDRH3*): a genotype-phenotype relationship that is important in determining severity risk in childhood asthma.¹³¹

GWAS have also identified asthma susceptibility loci associated with lung function, a fundamental determinant of asthma severity.^{132,133} A SNP in the *IL-6 receptor* gene (rs4129267, *IL6R*) has been associated with asthma in a large GWAS and was among the top SNPs associated with baseline lung function in a GWAS of the Framingham Heart Study cohort.^{106,134} This *IL6R* SNP is in LD with a coding variant (Asp³⁵⁸Ala) where the minor allele (Ala³⁵⁸) is associated with lower baseline lung function and increased methacholine bronchial responsiveness.¹³⁵ IL-6 is a proinflammatory cytokine expressed in inflammatory diseases such as asthma and COPD, and represents a potential therapeutic target because IL-6 receptor antagonists are available for the treatment of rheumatoid arthritis.¹³⁶⁻¹³⁸

Li and coworkers performed a meta-analysis of 14 SNPs previously associated with lung function in GWAS of controls from the *Cohorts for Heart and Aging Research in Genomic Epidemiology* (CHARGE) and SpiroMeta consortia. This analysis demonstrated that SNPs in the gene encoding for *hedgehog-interacting protein* (*HHIP*) were significantly associated with lung function in African American and non-Hispanic White asthma subjects. In addition, an increase in

the number of risk alleles for SNPs in *HHIP*, *PTCH1*, and *FAM13A* resulted in a significant stepwise decrease in lung function.¹³⁹ More recent studies have shown that Th1 immunity pathway genes (*IL12A*, *IL12RB1*, *STAT4*, *IRF2*) also appear to influence lung function and severity in asthma.¹⁴⁰

Elevated serum IgE is a primary associated phenotype for allergy in asthma. Two large GWAS of general population cohorts from the GABRIEL and EVE consortia have identified SNPs in *FCER1A* on chromosome 1q23, *RAD50*, *STAT6*, *IL13*, and the HLA complex associated with serum IgE concentrations, confirming prior linkage and association studies.^{33,34,39,72,73,98-100,141-145}

In non-Hispanic whites, four SNPs in the chromosome 11 open reading frame and the leucine rich repeat containing 32 gene (*C11orf30-LRRC32*) were associated with serum IgE.¹⁴⁶ The *C11orf30-LRRC32* genomic region contained SNPs associated with other inflammatory diseases such as atopic dermatitis, childhood eczema, and Crohn disease.¹⁴⁷⁻¹⁴⁹

Blood eosinophil levels and eosinophilic inflammation are related to asthma pathogenesis and severity and have been evaluated by GWAS. In a general population sample from Iceland and replication cohorts from Europe and East Asia SNPs in *IL1RL1* (rs1420101), chromosome 2q13 (rs12619285), chromosome 3q21 (rs4857855), chromosome 5q31 (rs4143832), and *SH2B3* on chromosome 12q24 (rs3184504) were associated with peripheral blood eosinophilia. The *IL1RL1* locus has been associated with asthma and loci in *WDR36* and *IL33* showed suggestive associations with eosinophil counts and atopic asthma.¹⁵⁰ Loci adjacent to *WDR36* (*TSLP*), *IL1RL1*, and *IL33* have also been associated with asthma in prior GWAS.^{73,109} Fraction of exhaled nitric oxide, a biomarker of eosinophilic airway inflammation, was evaluated in a GWAS in 14 pediatric cohorts that included asthmatics and control subjects. This GWAS identified loci associated with childhood exhaled nitric oxide levels in two genes on chromosome 17q11.2-q12, *LYRM9* and inducible nitric oxide synthase-2 (rs944722, *NOS2*), and adjacent to a previously replicated asthma susceptibility locus, *GSDMB* (rs8069176).¹⁵¹

Chitinases are a family of conserved hydrolases that cleave chitin and mediate Th2-driven airway inflammation in murine models.¹⁵² YKL-40 is a chitinase-like protein that has been evaluated as a biomarker for airway inflammation and remodeling in asthma. Serum YKL-40 levels are elevated in asthmatics and have been associated with disease severity.¹⁵³ A GWAS identified a SNP in the promoter of the chitinase 3-like 1 gene, which was associated with serum YKL-40 levels, asthma diagnosis, bronchial responsiveness, and lung function in an isolated population (Hutterites).¹⁵⁴

GWAS of lung function and inflammatory biomarkers have identified genes that impact disease severity. The impact of “lung function genes” on asthma severity provides an excellent example of how genetic markers from different genes can contribute to disease severity in an additive manner.¹³⁹ Gene variants important in asthma susceptibility likely differ from genes that cause asthma progression and severity. This concept is outlined in Figure 45-5, which proposes mechanisms by which susceptibility and severity genes interact in the development and progression of asthma.¹⁴⁰ Thus, susceptibility to asthma is genetically

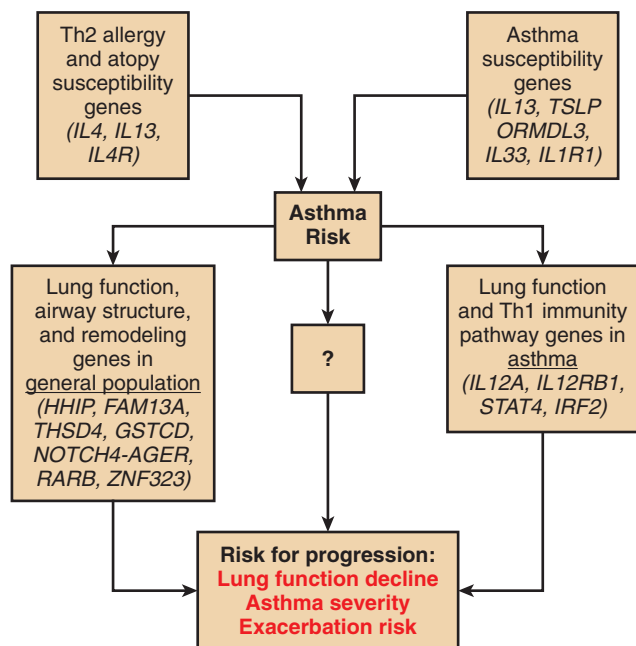

Figure 45-5 Genetic factors determine susceptibility and severity of asthma through independent pathogenic pathways. This flow diagram demonstrates how susceptibility loci for asthma and related phenotypes (including allergic or atopic characteristics) contribute to risk for asthma. In turn, different genetic determinants for lung function such as loci that accelerate airway remodeling or alter early lung development in combination with altered T type 1 helper (Th1) innate immunity in response to infection result in asthma progression. Many of the genes for risk of asthma susceptibility, progression, and severity are from different gene pathways. (Adapted from Li X, Hawkins GA, Ampleford EJ, et al: Genome-wide association study identifies Th1 pathway genes associated with lung function in asthmatic patients. *J Allergy Clin Immunol* 132:313–320 e15, 2013. Figure 3.)

determined by the gene variants identified in GWAS of asthma susceptibility. Disease progression is modulated by additional genes that determine asthma severity. For example, if the genome of an individual has gene variants conferring asthma susceptibility and also contains gene variants that encode for reduced lung function, this additive combination will result in the expression of a more severe asthma phenotype.¹³⁹ Furthermore, genetic markers of asthma severity could be used to generate genetic profiles that predict risk for disease progression.^{6,155}

GENE-ENVIRONMENT INTERACTIONS: GENETIC AND EPIGENETIC STUDIES FOR ASTHMA SUSCEPTIBILITY AND SEVERITY

Environmental factors have an important role in the pathogenesis of asthma and gene-environment interactions have been identified for asthma susceptibility and severity. Gene-environment interactions have the potential to identify factors that contribute to the missing heritability not accounted for by the effects of gene variants alone. Environmental cigarette smoke exposure is the most replicated environmental factor impacting genetic studies for

asthma susceptibility. Linkage studies in families from the CSGA cohort in the United States and The Netherlands both identified a linkage signal for asthma susceptibility and bronchial responsiveness on chromosome 5q31 that was dependent on passive cigarette smoke exposure.^{17,41} Another linkage study in French families from the EGEA (*Epidemiological Study on the Genetics and Environment of Asthma*) cohort also detected linkage for markers on chromosome 17q12 that was dependent on a gene-environment interaction with smoke exposure.^{42,43} In a family-based association study of 36 SNPs from the chromosome 17q12 in the *ORMDL3* region in the EGEA cohort, Bouzigon and coworkers¹⁵⁶ demonstrated 11 SNPs associated with an increased risk for asthma; however, the risk for early-onset asthma for the SNP with the strongest association (rs8069176) was 2.9 times greater in the subgroup exposed to cigarette smoke compared with the unexposed subgroup. These effects may be mediated by epigenetic regulation and demonstrate the complexity and interaction of genetic and environmental interactions in the pathogenesis of asthma.

Dietary factors such as vitamin D deficiency are associated with asthma development and severity.^{157,158} A genome-wide family-based association study identified genetic risk factors that interact with serum vitamin D levels affecting asthma severity. Three SNPs in the class I MHC-restricted T cell-associated molecule gene (*CRTAM*) were associated with an increased frequency of asthma exacerbations with low vitamin D levels. *CRTAM* is expressed in lung and by natural killer T and CD8⁺ cells; therefore, it is plausible that these gene variants interact with vitamin D, altering the immune response to viral infections.¹⁵⁹

The list of genes associated with asthma or related phenotypes is large and demonstrates that there are a number of biologic pathways important in asthma pathogenesis (see eTables 45-1 and 45-2). However, with the use of systems biologic approaches, there is potential for the development of genetic risk and severity profiles that can be used for early disease diagnosis and prediction of asthma progression.⁴

PHARMACOGENETICS OF ASTHMA

RATIONALE FOR PHARMACOGENETIC RESEARCH IN ASTHMA

Pharmacogenetics examines the role of gene variation in therapeutic responses to pharmacologic therapies. Pharmacogenetics is a gene-environment interaction wherein the therapeutic agent is the environmental exposure. There is evidence that genetic factors play an important role in the observed variability in therapeutic responses to different drugs. Approximately, 70% to 80% of asthmatics show varying responses to common antiasthma therapies, resulting in a marked variance in therapeutic drug responses.¹⁶⁰ Genetic variation might contribute to a large percentage of the variability in drug response, whether beneficial or adverse.^{160,161} The rationale for pharmacogenetic studies in asthma is that genetic markers could be used to identify subgroups of nonresponders, responders, or a subgroup at risk for adverse responses.

Pharmacogenetic research in asthma is driven by two major challenges related to asthma management. First, a small subgroup of approximately 5% to 10% of asthmatics experiences uncontrolled symptoms and recurrent exacerbations despite treatment with multiple antiasthma therapies, including high doses of inhaled or oral corticosteroids.^{8,9} This population with refractory asthma experiences substantial morbidity and generates a major financial burden compared to those with controlled mild or intermittent asthma.¹⁶² Second, adverse effects have been associated with some asthma therapies, particularly rare, life-threatening events associated with the use β_2 -adrenergic receptor agonists (i.e., β -agonists).^{10,11,163} Pharmacogenetic studies have the potential to identify genetic markers that would personalize therapeutic approaches in individual asthmatics to optimize therapeutic response and prevent adverse side effects.⁴

Pharmacogenetic studies of asthma therapies have been based on the primary clinical end points used in asthma clinical trials. In most pharmacogenetic studies, these predetermined clinical end points are analyzed for genetic associations with candidate gene studies or GWAS after the clinical trial is completed. These pharmacogenetic studies are important for the identification of genes or gene variants that influence drug responses. A minority of pharmacogenetic studies employs a prospective, genotype-stratified study design in which DNA is collected and genotyped for a risk variant of interest and subjects are randomized based on their genotype to treatment or placebo groups.¹⁶⁴ The advantage of a prospective, genotype-stratified approach is that it can ensure sufficient statistical power to analyze less common genetic variants because the population is recruited based on a predefined risk gene variant. However, a genotype-stratified pharmacogenetic trial is feasible if only a limited number (one or two) genotypes are being considered.

GLUCOCORTICOID PHARMACOGENETICS

Inhaled corticosteroids (ICS) have consistently been shown to be the most effective therapy to control persistent asthma.^{165,166} However, some asthmatics respond poorly to ICS.¹⁶⁷ The pharmacogenetics of the glucocorticoid pathway is based on genes that code for a complex pathway consisting of the glucocorticoid biosynthetic pathway, chaperone proteins, and the cytosolic receptor heterocomplex (eTable 45-3).¹⁶⁸

A candidate gene analysis of the *corticotropin-releasing hormone* (*CRHR1*) gene in more than 1000 asthma subjects from the National Institutes of Health and industry clinical trial cohorts identified two SNPs (rs242941 and rs1876828) that were associated with a change in lung function during ICS treatment.¹⁶⁷ In another study, the gene coding for a glucocorticoid receptor complex chaperone protein, the heat shock organizing protein (*STIP1*), identified three SNPs (rs2236647, rs6591838, and rs1011219) that were also associated with a significant change in lung function during ICS treatment.¹⁶⁹ The corticosteroid pathway interacts with other gene pathways that have been evaluated using a candidate gene approach in different clinical trial cohorts.^{170,171} The “T-box expressed in T-cells transcription factor” is encoded by *TBX21* and is an important regulator of the naive T-lymphocyte develop-

ment pathway. *TBX21* contains a coding SNP (rs2240017, His³³Gln) that was associated with “bronchoprotection,” that is, a reduction in bronchial hyperresponsiveness, during ICS treatment in the NHLBI *Childhood Asthma Management Program* (CAMP) and a Korean cohort.^{172,173} Adenyl cyclase type 9 is a key enzyme in the β_2 -adrenergic receptor pathway and is encoded by *ADCY9*, which contains a coding SNP (rs2230739, Met⁷⁷²Ile) that has been associated with an albuterol bronchodilator response in the CAMP cohort during ICS treatment.¹⁷⁴

Use of GWAS approaches has the potential to identify novel pharmacogenetic loci for ICS response. The first GWAS evaluating ICS treatment response was performed using family-based testing in CAMP followed by association studies for replication in more than 900 asthma subjects from four independent clinical trial cohorts. A promoter SNP in the glucocorticoid-induced transcript-1 gene (rs37972 in *GLCC11*) was associated with changes in lung function in response to ICS treatment. An in vitro study was also performed in which cells were transfected with another promoter variant in LD with rs37972 (rs37973) resulting in decreased gene expression.¹⁷⁵ These studies were primarily performed in children with fewer years of exposure to corticosteroids compared to adult asthmatics. Interestingly, more recent studies using large clinical trial cohorts of adult asthmatics were not able to replicate this association.¹⁷⁶ Functionally, *GLCC11* is an important regulator of apoptosis in response to glucocorticoids; therefore, this promoter variant may delay apoptosis of eosinophils during ICS therapy, thereby modulating therapeutic responses in asthma.¹⁷⁵

Another GWAS for ICS response was performed in asthma subjects from the NHLBI CAMP, *Asthma Clinical Research Network* (ACRN), and *Childhood Asthma Research and Education Network*. This GWAS identified SNPs in the *T* gene (rs3127412 and rs6456042) that were associated with changes in FEV₁ during ICS treatment. Subsequent detailed genotyping identified SNPs (rs3099266, rs2305089, rs1134481) within functional regions of the *T* gene.¹⁷⁷ Pharmacogenetic loci in the glucocorticoid pathway, *GLCC11*, and the *T* gene account for a small proportion of the interindividual variability for ICS therapeutic responses in asthma. It has yet to be determined whether these loci have additive effects with other pathway-related gene variants or are independent determinants of ICS response. Future pharmacogenetic studies in independent, large clinical trial cohorts or genotype-stratified trials are necessary to confirm and characterize these genes associated with ICS therapeutic responses and develop a genetic profile that may be used to predict therapeutic responsiveness to corticosteroids.

CYSTEINYL LEUKOTRIENE PHARMACOGENETICS

The cysteinyl leukotriene pathway is an inflammatory pathway containing potential pharmacogenetic loci for two classes of antiasthma therapies: 5-lipoxygenase (5-LO) inhibitors (e.g., zileuton) and cysteinyl leukotriene antagonists (e.g., montelukast and zafirlukast). The cysteinyl leukotriene biosynthetic pathway is initiated by 5-LO (encoded by *ALOX5*) followed by *leukotriene A₄ hydrolase* (*LTA4H*), and *leukotriene C₄ synthase* (*LTC4S*). Synthesized leukotrienes

	<i>ADRB2</i>	rs1042713 (Gly ¹⁶ Arg)	Candidate gene study	Long-term PEFR response	48–108	201, 203
Long-acting β-agonists (salmeterol and formoterol)			Retrospective and prospective, genotype-stratified	No effect on PEFR response	87–2655	201, 204–207
			prospective, genotype-stratified	Bronchoprotection	87, 152	207, 376
			prospective, genotype-stratified	Preference for montelukast or LABA as add-on to ICS	62	208

*Biologic candidate genes are summarized by drug class, associated polymorphisms (rs number and coding change, if relevant), study design, number of cohorts studied, population size, and response phenotype for which a pharmacogenetic effect has been detected.

ICS, inhaled corticosteroids; FEV₁, forced expiratory volume in 1 second; GWAS, genome-wide association study; LABA, long-acting β-agonists; PEFR, peak flow rate.

Reproduced from Ortega VE, Wechsler ME: Asthma pharmacogenetics: responding to the call for a personalized approach. *Curr Opin Allergy Clin Immunol* 13:399–409, 2013.

are transported to the extracellular space by *multidrug resistance protein 1* (MRP1) and activate *cysteinyl leukotriene receptors* (CYSLTR1 and CYSLTR2).

ALOX5 has a tandem repeat polymorphism in its promoter that has been associated with changes in lung function during treatment with leukotriene antagonists.^{178,179} An analysis of the cysteinyl leukotriene pathway in asthmatics treated with zileuton also identified SNPs in ALOX5 (rs892690, rs2029253, and rs2115819), LTC4S (rs272431), and MRP1 (rs215066 and rs119774) that were associated with changes in lung function during 5-LO inhibition.¹⁸⁰ Variation in leukotriene pathway genes has been reported in additional, smaller studies. These results support the finding that some of the variation in therapeutic responses to leukotriene modifiers is regulated by pharmacogenetic mechanisms (see eTable 45-3).^{90,180,182}

β₂-ADRENERGIC RECEPTOR PHARMACOGENETICS

Inhaled β-agonist treatment for asthma includes *short-acting β-agonists* (SABA) and *long-acting β-agonists* (LABA).¹⁸³ β-Agonists activate a G protein–coupled receptor pathway via adenylyl cyclase type 9 that regulates airway smooth muscle relaxation.¹⁷⁴ Inhaled β-agonists are the most commonly used treatment for asthma despite having been associated with very rare life-threatening adverse responses since the 1960s.¹⁸⁴⁻¹⁸⁸

While various analyses have attempted to explain these “mini-epidemics” of asthma mortality,^{10,11,184-191} the U.S. Food and Drug Administration issued a boxed warning for all LABA-containing inhalers regarding the risk for life-threatening exacerbations.¹⁹² This LABA safety controversy is being evaluated in 46,800 asthma subjects who are currently being recruited for the U.S. Food and Drug Administration–mandated international LABA safety study.^{192,193} Pharmacogenetic studies have attempted to identify genetic markers for β-agonist response to identify a subgroup that is susceptible to these serious adverse effects. These studies have primarily focused on genes related to the β₂-adrenergic receptor and nitric oxide synthetic pathways (see eTable 45-3).

The gene encoding the β₂-adrenergic receptor (ADRB2) has a single exon and is located on chromosome 5q31 with more than 49 polymorphisms identified.^{194,195} The most studied of these ADRB2 polymorphisms is the common coding variant, Gly¹⁶Arg.^{194,196} In vitro, receptors expressing the Gly¹⁶ variant show increased receptor down-regulation in response to β-agonist stimulation compared to Arg¹⁶.^{197,198}

Two early pharmacogenetic studies of ADRB2 in asthmatic children demonstrated that Arg¹⁶ homozygotes experienced a greater bronchodilator response to a single dose of albuterol compared to Gly¹⁶ homozygotes.^{91,92} This effect of Gly¹⁶Arg genotypes on acute SABA bronchodilator response was confirmed in small asthma populations.^{199,200} In contrast, pharmacogenetic studies of long-term, regular SABA treatment in two independent clinical trial cohorts demonstrated effects on therapeutic responses: Arg¹⁶ homozygotes experienced a decline in *peak flow rate* (PEFR) during chronic SABA treatment while Gly¹⁶ homozygotes did not experience changes in PEFR.^{201,202}

In a genotype-stratified, crossover trial, the ACRN, Gly¹⁶ and Arg¹⁶ homozygotes were randomized to treatment with regular albuterol or placebo. Gly¹⁶ homozygotes showed an increase in PEFR during regular albuterol treatment while Arg¹⁶ homozygotes showed no changes in PEFR with regular albuterol but had an increase in PEFR during as-needed albuterol treatment (Fig. 45-6). In addition, regular albuterol treatment resulted in decreased rescue inhaler use and asthma symptom scores in Gly¹⁶ homozygotes, while Arg¹⁶ homozygotes experienced a deterioration of these secondary outcomes.¹⁶⁴ Although the adverse effects of regular SABA treatment in Arg¹⁶ homozygotes are important to understand, asthma guidelines do not recommend regular scheduled SABA in asthma. However, regular scheduled LABA is used to control asthmatics who are symptomatic on ICS alone. Thus, pharmacogenetic effects related to LABA exposure would have major therapeutic implications.

The genotypic effects of Gly¹⁶Arg during long-term LABA therapy were evaluated in two small trial arms from larger NHLBI ACRN clinical trials. Results from these trials showed a potential for reduced effectiveness of LABA in Arg¹⁶

Figure 45-6 The Asthma Clinical Research Network Beta Agonist Response by Genotype (BARGE) Trial. The BARGE trial evaluated the effect of genotypes in response to regular short-acting β-agonist (albuterol) therapy or placebo given four times daily for 16-week treatment periods. For patients with the Gly/Gly genotype, the PEFR improved significantly more when they were treated with albuterol (red line) compared with placebo. In contrast, patients with the Arg/Arg genotype improved more when treated with placebo (blue line) compared with albuterol. PEFR, peak flow rate. (Adapted from Israel E, Chinchilli VM, Ford JG, et al: Use of regularly scheduled albuterol treatment in asthma: genotype-stratified, randomised, placebo-controlled cross-over trial. *Lancet* 364:1505–1512, 2004. Figure 3.)

homozygotes.²⁰³ Subsequent prospective clinical trials and pharmacogenetic analyses with larger cohorts including two genotype-stratified trials did not show evidence for reduced therapeutic effectiveness of LABA therapy in Arg¹⁶ homozygotes compared to Gly¹⁶ homozygotes.^{201,204-207} Interestingly, in one of these prospective genotype-stratified trials, Gly¹⁶ homozygotes experienced a more prolonged protection from methacholine-induced bronchoconstriction than was observed in Arg¹⁶ homozygotes.²⁰⁷ Another genotype-stratified study randomized 62 Arg¹⁶ homozygotes to either montelukast or LABA in addition to ICS therapy and demonstrated greater symptom control with the addition of montelukast. This study suggested that the Gly¹⁶Arg locus could interact with other therapies in asthma.²⁰⁸

In contrast to a common variant such as Gly¹⁶Arg that likely exhibits smaller effects, it is possible that rare genetic variants with strong effects might be responsible for some of the uncommon and severe adverse responses associated with LABA treatment in asthma (see Fig. 45-4). A rare variant within the fourth transmembrane domain of ADRB2, Thr¹⁶⁴Ile, results in a protein with decreased β_2 -adrenergic receptor ligand binding, coupling to G_s protein, and sequestration in response to SABAs and LABAs in vitro.^{209,210} This rare variant also significantly impairs the binding of salmeterol to its “exosite,” or secondary binding site, on the β_2 -adrenergic receptor.²¹⁰ The Ile¹⁶⁴ allele was associated with an increased risk of airflow obstruction and reduced lung function in a cross-sectional population-based study of nearly 60,000 subjects.²¹¹ Thr¹⁶⁴Ile and a 25 base pair insertion variant found only in African Americans, have also been associated with severe exacerbations requiring hospitalization in asthma patients treated with a LABA. Thr¹⁶⁴Ile has also been associated with poor symptom control during LABA treatment in two independent cohorts. This finding of a rare genetic variant and adverse LABA effects has the potential to identify a very important at-risk asthma subpopulation. Thus, rare variants such as those in ADRB2 are potential biomarkers for more personalized, precise guideline-based treatment strategies in the small subset of asthmatics that have altered responsiveness to the combination therapy of a LABA with ICS.²¹² In addition, a recent study combining admixture mapping and GWAS in Puerto Ricans and Mexican asthmatic children from GALA has identified rare variants in solute carrier genes associated with bronchodilator response to SABAs, providing further evidence for the role of rare genetic variation as pharmacogenetic loci.^{212a}

Association studies of candidate genes related to the β_2 -adrenergic receptor pathway have identified additional common polymorphisms that have been associated with the acute bronchodilator response to SABA. ADCY9 is a canonical β_2 -adrenergic receptor pathway gene with a common coding variant, Ile⁷⁷²Met, associated with increased acute FEV₁ bronchodilator response to albuterol during ICS therapy in children from the CAMP cohort.¹⁷⁴ The effect of Met⁷⁷²Ile genotypes on the bronchodilator response to β -agonists during ICS therapy was also reported in a Korean population treated with a LABA (formoterol).²¹³ CRHR2 is another pathway-related gene with SNPs that have been associated with the SABA response. CRHR2 encodes the corticotropin-releasing hormone receptor-2, a

G-coupled protein receptor that regulates relaxation of airway smooth muscle through a signaling pathway similar to that of the β_2 -adrenergic receptor (via activation of adenylyl cyclase and protein kinase A). Five SNPs in CRHR2 were associated with acute bronchodilator responses to SABA in asthma subjects from three independent clinical trial cohorts.²¹⁴

Association studies of genes indirectly related to the β_2 -adrenergic receptor pathway have identified variants within the nitric oxide biosynthetic pathway associated with acute SABA bronchodilator response. An association study of 111 genes from the β_2 -adrenergic receptor and glucocorticoid pathways in subjects from the CAMP cohort and three independent trial cohorts identified a SNP in *arginase 1* (ARG1), rs2781659, which was associated with an acute bronchodilator response.²¹⁵ SNPs in ARG2 have also been associated with a SABA bronchodilator response.²¹⁶ Arginase 1 and 2 metabolize L-arginine, which is a natural substrate for nitric oxide synthase, resulting in the production of nitric oxide. Nitric oxide is an endogenous bronchodilator; therefore, ARG1 and ARG2 polymorphisms may alter airway smooth muscle relaxation during β -agonist treatment.²¹⁷

Finally, a GWAS reported by Himes and colleagues²¹⁸ identified a novel genetic locus for acute SABA bronchodilator responses. The primary GWAS analyzed 1644 asthmatics from six clinical trial cohorts with replication assessed in 1051 subjects from SARP and a Dutch asthma cohort. A SNP within the promoter region of the *spermatogenesis associated, serine-rich 2-like* gene (rs295137 in SPATS2L) was associated with the acute bronchodilator response to albuterol. In human airway smooth muscle cells, the functional importance of SPATS2L in the β_2 -adrenergic receptor pathway was confirmed after a knockdown of this gene resulted in increased β_2 -adrenergic receptor expression.²¹⁸ The investigators also confirmed previous associations for three candidate genes for albuterol bronchodilator response: ADCY9, CRHR2, and ARG1.^{174,214,215,218}

LIMITATION OF CURRENT PHARMACOGENETIC ASSOCIATIONS AND FUTURE DIRECTIONS

Most of the pharmacogenetic associations for therapeutic response do not account for a significant amount of the variability in drug responses. In part, this is because multiple genes influence these responses. In addition, pharmacogenetic analysis was not the primary outcome of most of these studies and sample sizes were too small to assess single or multiple gene interactions. Furthermore, when the combination of a LABA and ICS are used, polymorphisms in the β_2 -adrenergic receptor pathway might result in a negative treatment response that interacts with polymorphisms in the same pathway or an alternative (i.e., glucocorticoid) pathway to obscure associations.

Pharmacogenetic studies have the potential to identify the subgroup of asthmatics who are more or less responsive to biologic therapies currently under development. Biologic therapies are more expensive and have the potential to cause unwanted adverse responses. Thus, pharmacogenetic therapeutic “biomarkers” that identify susceptible asthmatics should facilitate development and registration of biologic therapies. Pitracinra is a molecular inhibitor of the

IL4 α receptor subunit that inhibits both IL-4 and IL-13, which are important in the regulation of Th2 allergic inflammation. In a phase 2b clinical trial, specific variants in the gene coding for the *IL4 α receptor subunit* (*IL4RA*) have been associated with changes in antigen-induced bronchial hyperresponsiveness in atopic asthmatics treated with pirarctinra, and improvements in asthma exacerbation frequency.^{93,102} These results are an excellent example of the use of a pharmacogenetic “biomarker” to identify the subset (approximately 35 percent) of responders to this IL4 α receptor antagonist.

Pharmacogenetic studies in asthma had initially been limited to candidate gene studies in smaller clinical trial cohorts; however, investigators have more recently performed GWAS which have identified novel pharmacogenetic loci (see eTable 45-3). *In vitro* studies have been used to validate the function of these SNPs. Future pharmacogenetic studies in independent, large clinical trial cohorts or genotype-stratified trials will be necessary to evaluate the importance of these gene variants, to confirm previous associations, and to determine whether these polymorphisms act independently or have additive effects on therapeutic responses to ICS, inhaled β -agonists, leukotriene modifiers, and other, newer asthma therapies. Understanding the pharmacologic and genetic basis of therapeutic responsiveness in asthma may lead to the development of more effective therapeutic agents. These approaches, when performed in adequately powered pharmacogenetic trials using unbiased methodology (GWAS), have delineated genetic determinants of pharmacologic treatment, with both beneficial and adverse responses, in other complex diseases such as those currently under investigation in the National Institutes of Health Pharmacogenomics Research Network.^{219,220} Thus, future precise therapeutic approaches in asthma will include the use of genetic pharmacogenetic profiles.

GENETIC STUDIES OF COPD SUSCEPTIBILITY

EVIDENCE THAT LUNG FUNCTION IMPAIRMENT AND COPD ARE HERITABLE

COPD results from the interaction of different genetic factors and environmental exposures. COPD is a common, complex, and heterogeneous airway disease characterized by chronic bronchitis, mucus hypersecretion, emphysema with the loss of elastic recoil, and destruction of small airways.²²¹ Tobacco smoke is the most common environmental exposure known to cause COPD while biomass smoke is an established exposure in developing countries.²²²⁻²²⁴ The diagnosis of COPD is based on spirometric measurements, and the severity of COPD, in part, is based on the level of FEV₁ as the percentage predicted.² Thus, the major phenotype for genetic studies evaluating COPD susceptibility and severity is the presence and degree of airflow obstruction. This definition raises an important question: how to interpret genetic associations with reduced lung function in a disease defined by airflow obstruction? The question becomes whether disease susceptibility genes are related

directly to reduced pulmonary function or whether lung function modifier genes accelerate loss of pulmonary function over time.

There is evidence of overlap between gene variants associated with disease severity in asthma and COPD cohorts. Similar genetic associations have been reported for lung function in both obstructive airway diseases. In addition, exposure to tobacco smoke (passive and active) alters asthma phenotypes.^{139,225} Genetic studies related to COPD susceptibility usually adjust for environment interactions with tobacco smoke exposure due to its strong association with risk for COPD. Despite this strong association, lung function decline is highly variable among unrelated cigarette smokers, suggesting genetic factors as well as environmental exposures are important in the pathogenesis of COPD.²²⁶

Family and twin-based studies demonstrate that lung function has an estimated heritability up to 100% and that 20% to 60% of the variance in lung function could be influenced by familial factors.^{45,46,227-232} Epidemiologic studies have demonstrated that COPD is more prevalent among the relatives of individuals with COPD than in a population of unrelated individuals, strongly suggesting heritable factors.²³³ However, these factors do not follow a simple mendelian pattern of inheritance because of interactions between multiple genetic and environmental factors.^{228,234,235} Heritability in COPD was demonstrated in a study in which first-degree relatives of probands with COPD had a lower FEV₁ and FEV₁/FVC ratio than unrelated controls. In addition, reduced lung function was only identified in first-degree relatives who had currently or previously smoked cigarettes, suggesting interactions between hereditary and environmental influences.²³⁶ The evidence of heritable factors for COPD susceptibility provides a rationale for genetic studies to identify genes that confer susceptibility and risk for disease progression and severity.

FAMILY-BASED LINKAGE STUDIES FOR LUNG FUNCTION IMPAIRMENT AND COPD

In contrast to asthma, COPD is an adult-onset disease and therefore has been studied less often by family-based linkage studies and mostly by case-control population-based studies including GWAS. The only single gene variants (mendelian) known to be directly associated with COPD are in genes coding for *serpin peptidase inhibitor, clade A (α_1 -antitrypsin), member 1* (*SERPINA1*) on chromosome 14q31 for which more than 100 rare variants have been identified as genetic determinants for emphysema and COPD.²³⁷ The relationship between α_1 -antitrypsin (A1AT) deficiency and emphysema was initially described in 1964; however, it was not until 1976 that gene variants in *SERPINA1* were identified as the cause of A1AT deficiency.²³⁸⁻²⁴⁰ A1AT deficiency is inherited through an autosomal codominant pattern of inheritance resulting in a rare, early-onset obstructive lung disease accounting for only 1% to 2% of all cases of COPD.²⁴¹ Thus, variants in other genes contribute to the pathogenesis of COPD in the vast majority.

Most linkage studies for COPD susceptibility have evaluated lung function in related subjects from the general population or susceptibility in families ascertained through

probands diagnosed with early-onset COPD.^{45-47,242} A linkage study in a Hutterite general population identified a locus linked to FEV₁/FVC ratio on chromosome 5q33, which was confirmed in a Utah reference population.^{45,46} The first linkage studies for susceptibility to COPD and lung function were performed in a cohort of families with severe, early-onset COPD by the *Boston Early-Onset COPD* (BEOCOPD) study group, which identified linkage at loci on chromosome 12p12 and 19q for both moderate airflow obstruction (FEV₁ < 60% of predicted) and mild airflow obstruction (FEV₁ < 80% of predicted).^{47,242}

Detailed mapping of the chromosome 12p region in COPD cases and controls from the *National Emphysema Treatment Trial* (NETT) and the *Normative Aging Study* (NAS) subsequently identified a SNP associated with COPD in the *SRY* (*sex determining region Y*)-box 5 gene (*SOX5*). Detailed mapping of the chromosome 19q region identified SNPs in the *transforming growth factor-β1* gene (*TGFB1*) as associated with COPD.²⁴³ Interestingly, both regions on chromosome 12p and 19q have also been identified as susceptibility loci for asthma.^{24,26} *SOX5* functions in lung development while *TGFB1* codes for a proinflammatory cytokine that has been intensively studied as a candidate gene for COPD.^{244,245} The *TGFB1* locus on chromosome 19q was identified as a COPD susceptibility locus and was associated with COPD in the BEOCOPD cohort.^{243,251-254} A *TGFB1* promoter SNP has also been associated with asthma susceptibility and severity.²⁴⁶⁻²⁴⁹ *TGFβ1* is a multifunctional cytokine secreted by airway epithelial cells, macrophages, fibroblasts, and Th2 lymphocytes to regulate cellular growth and development, tissue repair and fibrosis, and inflammatory immune responses.²⁴⁴

Other studies from the BEOCOPD cohort identified evidence of linkage for loci on chromosome 2q with baseline FEV₁ and FEV₁/FVC. This locus on chromosome 2q was also linked with a very high likelihood (LOD score of approximately 5) to FEV₁/FVC in Dutch families with asthma.^{18,47} These early genetic approaches in COPD identified relevant biologic COPD susceptibility genes and also showed evidence that some of these genetic loci overlap with asthma loci, thus providing evidence for pathogenic similarities in asthma and COPD.^{18,24,26,47,242}

CANDIDATE GENE ASSOCIATION STUDIES FOR LUNG FUNCTION AND COPD

Initial candidate gene association studies for COPD susceptibility focused on genes from inflammatory, protease-antiprotease, and oxidant-antioxidant pathways (eTable 45-4). These early studies were limited by small cohorts, absence of a standardized COPD diagnosis, and analyses that did not adjust for population stratification. Two meta-analyses of 12 candidate genes demonstrated that most gene variants previously associated with COPD were not true associations.^{250,251} The loci that have been consistently associated with susceptibility to COPD include *TGFB1*, *GSTM1*, *GSTP1*, *ADAM33*, and *MMP12* (see eTable 45-4).^{54,56,243,252-255}

ANTIOXIDANT PATHWAY GENES AND COPD SUSCEPTIBILITY

Genes within the antioxidant pathway regulate the metabolism of reactive oxygen and nitrogen species delivered from tobacco smoking and, thus, are appropriate biologic candidate genes for COPD (see eTable 45-4). The most extensively studied antioxidant pathway-related genes include those that code for microsomal *epoxide hydrolase* (*EPHX1*) and *glutathione S-transferase* (*GST*) subunits *Pi-1*, *Mu-1*, and *Theta-1* (*GSTP1*, *GSTM1*, *GSTT1*). Small association studies of polymorphisms in *EPHX1*, *GSTP1*, and *GSTM1* have shown significant associations with COPD.^{250,251,256-264} Subsequent meta-analyses have combined these studies to confirm variant associations for COPD susceptibility with antioxidant pathway genes in different population-based cohorts.^{251,265} In addition, polynucleotide deletions at *GSTM1* and *GSTT1* have been associated with lung function decline in subjects from the Swiss Cohort Study on Air Pollutants and Lung and Heart Diseases in Adults cohorts demonstrating the importance of gene-gene interactions in COPD.²⁶⁶

ADAM33 IS A LOCUS FOR ACCELERATED LUNG FUNCTION DECLINE AND COPD

ADAM33 is among the most replicated genes for asthma susceptibility and associations with lung function decline in asthma subjects.^{21,50-52,55} *ADAM33* polymorphisms have been associated with lung function decline and baseline airflow obstruction in general population cohorts, suggesting a role for *ADAM33* in the pathogenesis of COPD (eTable 45-5).⁵⁶ An association study of *ADAM33* in long-term smokers identified five SNPs significantly associated with COPD defined by lung function, suggesting that *ADAM33* is a susceptibility locus for COPD and pulmonary function abnormalities in cigarette smokers.⁵⁴

MMP12 AND COPD SUSCEPTIBILITY

The gene coding for *matrix metalloproteinase 12* (*MMP12*) has a promoter SNP (rs2276109) associated with lung function and COPD in a large association study of seven independent cohorts totaling 8300 subjects. *Reference sequence* (rs)2276109 was associated with COPD and lung function in prior cigarette smokers but not among never-smokers.²⁵⁵ *MMP12* is highly expressed in alveolar macrophages from cigarette smokers compared to non-smokers and appears to have important functions in the development of emphysema during cigarette smoke exposure.^{267,268}

GENOME-WIDE ASSOCIATION STUDIES OF LUNG FUNCTION IN THE GENERAL POPULATION

Decreased pulmonary function is important in the diagnosis of COPD, for the characterization of disease severity, and as a predictor of overall survival.^{44,269} GWAS for lung

*Candidate genes for lung function are categorized by molecular pathway. These loci have been identified through linkage studies, genome-wide association studies (GWAS), or candidate gene association studies in the general population and further characterized in COPD study cohorts. Genes are summarized by full gene name, gene identification (ID) acronym, initially reported locus (by single nucleotide polymorphism rs number), and associated phenotypes.

function, performed in general population cohorts, have provided insight into mechanisms that contribute to an accelerated loss of lung function and impairment in baseline pulmonary function in both COPD and asthma (see eTable 45-5). GWAS in two general populations derived from large cardiovascular epidemiology cohorts have identified candidate genes from different biologic pathways that have a potential biologic role in the susceptibility and progression of COPD and emphysema.^{134,270-272} It is important to note that these general populations may have included subjects with unrecognized asthma, COPD, or emphysema; however, these GWAS are very large and represent genetic loci for lung function genes that primarily reflect these general population samples. In both asthma and COPD, it has been useful to study candidate genes for lung function identified in these general population studies to identify genetic loci that may contribute to reduced lung function and, thus, in COPD to susceptibility and severity. These candidate genes are discussed in the context of their initial identification in general populations as well as biologic plausibility and studies in cohorts with established COPD.

GSTO2 AND IL6R AS LOCI FOR LUNG FUNCTION

The first GWAS for lung function was performed in the Framingham Heart Study cohort and identified a coding SNP in *glutathione-S-transferase omega-2* (*GSTO2*) on chromosome 10q25 (Asn¹⁴²Asp, rs156697) that was associated with FEV₁ and FVC, and a SNP in *IL6R* (rs4129267) that was associated with forced expiratory flow rates.¹³⁴ The soluble IL-6 receptor forms a complex with IL-6, which is involved in the inflammatory responses initiated by cigarette smoke exposure. IL-6 levels are elevated in the airways of subjects with COPD compared to healthy nonsmokers.²⁷³⁻²⁷⁵ Sputum and serum IL-6 concentrations increase during COPD exacerbations and have been associated with reduced lung function and accelerated lung function decline in subjects with COPD, asthma, and the general population.^{136,276-278} *IL6* variants have been associated with serum IL-6 concentrations in control subjects from the Cardiovascular Health Study as well as COPD and accelerated lung function decline in other cohorts.²⁷⁹⁻²⁸¹ The *IL6R* locus has also been associated with asthma susceptibility in a GWAS of European white subjects and is in LD with a coding SNP in *IL6R*, Asp³⁵⁸Ala, associated with lung function in more severe asthma, demonstrating the overlapping biologic mechanisms in these obstructive airway diseases.^{106,135}

HEDGEHOG-INTERACTING PROTEIN GENE AS A LOCUS FOR LUNG FUNCTION

Large GWAS for lung function, the CHARGE and the SpiroMeta consortia (general population samples), identified SNPs on chromosome 4q31 in *HHIP* as associated with FEV₁/FVC ratio.²⁷⁰⁻²⁷² *HHIP* regulates the hedgehog signaling important in lung branching morphogenesis and airway smooth muscle differentiation in murine models.²⁸²⁻²⁸⁴ Altered lung development might result in impaired respiratory reserve and increase the risk for COPD, particularly during exposure to tobacco smoke. Subsequent association studies have confirmed the role of gene variants in *HHIP* as

an important gene in COPD susceptibility.²⁸⁵⁻²⁸⁸ In addition, gene variants in *HHIP* have also been associated with reduced lung function in asthma, demonstrating evidence for overlapping genetic regulation of lung function in these two diseases.¹³⁹

TWO LARGE GENERAL POPULATION CONSORTIA IDENTIFY SEVEN LOCI FOR LUNG FUNCTION

Two large meta-analyses by the CHARGE and SpiroMeta consortia identified seven novel loci for lung function (see eTable 45-5).^{271,272} These loci regulate processes related to lung development (*ADAM19*, *GPR126*), inflammation (*HTR4*, *THSD4*), tissue remodeling (*ADAM19*, *AGER*, *HTR4*, *THSD4*, *TNS1*), and the antioxidant pathway (*GSTCD*). These gene targets have been evaluated in subsequent association studies. For COPD, SNPs in *TNS1*, *GSTCD*, *HTR4*, *AGER*, and *THSD4* were associated with COPD susceptibility and severity (lung function) in 12 population-based cohorts. In addition, a six-SNP (0 to 12 alleles) risk score incorporating risk variants from *TNS1*, *GSTCD*, *HTR4*, *AGER*, *THSD4*, and *HHIP* resulted in a stepwise decrease in pulmonary function and increase in COPD risk in subjects with a greater number of risk variants.²⁸⁷ This additive, detrimental effect of risk variants on lung function has also been reported in asthma subjects.¹³⁹ A large-scale meta-analysis of the combined CHARGE and SpiroMeta consortia (a joint analysis of 94,612 non-Hispanic whites) identified loci on or near 16 additional genes associated with lung function in the discovery and replication cohorts, further demonstrating the complex genetic factors that influence lung function in the general population.²⁸⁹ While these loci have been associated with lung function in the general population, some of these loci represent plausible biologic candidate genes for the susceptibility or severity of obstructive airway diseases.

AGER codes for the *advanced glycosylation end product receptor* (*AGER*), which regulates the production of IL-6, TNF- α , and matrix metalloproteinases. A coding SNP in *AGER* (Gly⁸²Ser), associated with FEV₁/FVC, results in enhanced ligand binding affinity and increased cytokine/MMP production upon receptor activation.²⁹⁰ *AGER* is expressed in the human lung and has been implicated in idiopathic pulmonary fibrosis.^{291,292} *HTR4* codes for *5-hydroxytryptamine* (5-HT or serotonin) receptor-4. Activation of the 5-HT₄ receptor in airway epithelial cells promotes the production of proinflammatory cytokines, including IL-6, an inflammatory biomarker for lung function and COPD.²⁹³ *THSD4* (encodes thrombospondin, type 1, domain containing-4 gene) and *TNS1* (encodes tensin-1) potentially contribute to airway remodeling through altered signal transduction in pathways that regulate cell migration, proliferation, and adhesion in the setting of inflammation.²⁹⁴⁻²⁹⁶

ADAM19 has not been implicated in lung disease but is expressed in alveolar epithelial cells and airway smooth muscle cells.²⁹⁷ Like other ADAM proteins, including *ADAM33*, *ADAM19* has the potential to regulate proteolytic activity, cell-matrix interactions, and lung morphogenesis.^{48,49} *GPR126* codes for an adhesion G-coupled protein receptor essential for cell-cell and cell-matrix interactions

during organ development and has been consistently associated with adult height.²⁹⁸⁻³⁰¹ These gene variants in *ADAM19*, *HHIP*, and *GPR126* may affect lung development, resulting in impaired respiratory function.²⁸⁴

GENOME-WIDE ASSOCIATION STUDIES FOR COPD SUSCEPTIBILITY

α -NICOTINIC ACETYLCHOLINE RECEPTOR 3/5 GENES AS LOCI FOR COPD SUSCEPTIBILITY

The first GWAS for COPD susceptibility identified SNPs in the gene coding for the α -nicotinic acetylcholine receptor [*CHRNA3* and *CHRNA5* (*CHRNA3/5*)] on chromosome 15q25. In the BEOCPD cohort, *CHRNA3/5* was associated with baseline FEV₁.²⁸⁸ The genomic region on chromosome 15q25 tagged by these SNPs spans other genes, including *IREB2*, which have been associated with COPD in subsequent studies.³⁰² These findings suggest a gene-environment interaction on chromosome 15q25 that may modulate COPD susceptibility. Variants in *CHRNA3/5* alter nicotine dependence pathways resulting in enhanced nicotine addiction and a reduced likelihood for cigarette smoking cessation leading to the development of COPD. Interestingly, this gene has also been associated with lung cancer in cigarette smokers, suggesting overlapping mechanisms perhaps related to tobacco dependence or effects on lung inflammation^{303,304} (see Chapter 51). Alternatively, variants in a neighboring gene, *IREB2*, directly alter the antioxidant pathway, an important biologic factor for COPD susceptibility.^{302,305,306}

Two GWAS and multiple candidate gene studies have confirmed the role of *CHRNA3/5* as a locus for nicotine addiction.³⁰³⁻³¹⁰ Altered nicotine addiction and COPD risk is supported by the identification of *CYP2A6* (key enzyme for the conversion of nicotine to cotinine) as another locus that has been associated with both nicotine addiction and COPD risk.^{307,311-313} However, the *CHRNA3/5* locus contains variants in LD with SNPs in an adjacent gene *IREB2*, which codes for the iron-responsive element binding protein-2. Iron regulatory proteins regulate iron uptake, distribution, and metabolism and are activated at lower oxygen tensions.³¹⁴ Iron and iron-binding proteins show regional variability in the lungs of smokers, which may result in differences in the production of proinflammatory mediators in response to iron accumulation.^{315,316} Thus, gene variants in *IREB2* may alter the burden of oxidative injury to the lung in response to cigarette smoking and promote the development of COPD. An integrative approach identified altered gene expression of *IREB2* in lung tissue from patients with COPD, and subsequently three SNPs in *IREB2* were associated with COPD and lung function in subjects from the NETT, BEOCPD, and the International COPD Genetics Network cohorts.³⁰²

FAM13A AS A COMMON LOCUS FOR COPD AND LUNG CANCER SUSCEPTIBILITY

A second larger GWAS for COPD susceptibility performed in current or former smokers from a large international

consortium on COPD genetics [Norway, NETT, NAS, and the multicenter *Evaluation of COPD Longitudinally to Identify Predictive Surrogate End-points* (ECLIPSE) Studies] identified two SNPs in *FAM13A* on chromosome 4q22 significantly associated with COPD and replicated in the COPD Gene Study cohort and in families from BEOCPD and International COPD Genetics Network.³¹⁷ These findings are consistent with GWAS results from earlier studies for determinants of lung function impairment in general populations (CHARGE consortium).²⁷² *FAM13A* codes for the family with sequence similarity 13, member A protein and is differentially expressed in epithelial and endothelial cells in response to hypoxia.³¹⁸ It is also expressed in human alveolar type II cells during epithelial cell differentiation and is differentially expressed in cystic fibrosis.^{319,320} *FAM13A* variants have been associated with lung cancer, suggesting that this locus is a common genetic factor for these pulmonary diseases.^{321,322} *FAM13A* SNPs have not been associated with pack-years of cigarette smoking nor does adjustment for pack-years impact these associations.^{317,321,322} This factor may relate to a *Rho-GTPase-activating protein* (Rho-GAP) domain within the second to fifth exons of *FAM13A*, which may have tumor suppressor activity or impair clearance of apoptotic alveolar macrophages in response to oxidative stress from cigarette smoke exposure.³²³⁻³²⁷

CYP2A6 AS A LOCUS FOR COPD SUSCEPTIBILITY

Recent GWAS for COPD susceptibility (ECLIPSE, NETT, Norway COPD, COPD Gene, and NAS cohorts) identified a novel susceptibility locus on chromosome 19q13, which has been replicated. This COPD susceptibility locus contains genes encoding a *RAB protein* (*RAB4B*), a *melanoma inhibitory variant* (*MIA*), *EGL nine homolog 2* (*EGLN2*), and *cytochrome P-450 2A6* (*CYP2A6*) (see eTable 45-4).³¹³ *RAB4B*, *MIA*, and *EGLN2* are expressed in the developing lungs of animals and humans and thus may regulate lung development and baseline respiratory reserve.³²⁸⁻³³⁰ The *CYP2A6* locus codes for a key enzyme responsible for the metabolism of nicotine to cotinine and has been consistently associated with smoking behavior in multiple independent cohorts.^{307,311,312} The *CYP2A6* locus has also been associated with both smoking behavior and lung cancer in independent cohorts.^{312,331} The association of the same gene variants for COPD and lung cancer supports the overall importance of overlapping biologic mechanisms that may be present for both of these diseases.

GWAS FOR EMPHYSEMA, A COPD-RELATED PHENOTYPE

While initial GWAS for COPD susceptibility were based on lung function analyses, there have been more recent studies evaluating genetic determinants of emphysema. Emphysema can be diagnosed using lung density with computed tomography. Early candidate gene studies for emphysema analyzed genes in the protease-antiprotease and antioxidant pathways in small cohorts and reported associations between emphysema-specific phenotypes and *MMP9* and *EPHX1* (see eTable 45-4).^{256,332-334}

The first GWAS for emphysema was performed using phenotypes characterized by both quantitative (presence versus

absence of emphysema) and qualitative methods (measure of lung density < -950 Hounsfield units) in COPD subjects in the ECLIPSE, NETT, and Norway cohorts. In a combined meta-analysis, a SNP in the gene encoding a homolog for the *Drosophila* gene *bicaudal D homolog 1* (*BICD1*) on chromosome 12p11 was associated with emphysema based on the qualitative method.³³⁵ The associated *BICD1* locus covers a genomic region that contains a coiled-coil domain important for dynein-mediated intracellular processes including mitosis, mRNA transport, and vesicular transport.³³⁶⁻³³⁸ Another regulatory *BICD1* SNP was associated with leukocyte telomere length in an independent genome-wide linkage analysis.³³⁹ Telomeres maintain the integrity of chromosomes and shorten during the aging process, resulting in different age-related diseases; therefore, *BICD1* is a locus that potentially links aging with emphysema or COPD through altered epithelial integrity.^{340,341} Mechanistic evidence for this link is based on studies in telomerase-null mice that develop emphysematous air space enlargement during chronic exposure to cigarette smoke.³⁴⁰

While this list of gene targets related to COPD susceptibility and severity seem diverse and complex, a composite of regulatory genes and pathways is developing. These risk genotypes can be combined with clinical risk factors and COPD phenotypes (including pulmonary function, comorbidities, and imaging assessment of emphysema) to develop “clinical genetic profiles” for risk prediction for COPD susceptibility and severity. Furthermore, these genes can be evaluated as potential disease-modifying therapeutic targets in COPD.

PHARMACOGENETICS OF COPD

RATIONALE FOR PHARMACOGENETICS IN COPD

The most commonly used medical therapies for COPD include LABA, *long-acting antimuscarinics* (LAMA) and ICS therapy for long-term management with SABA and short-acting antimuscarinics used for as-needed rescue therapy. Most pharmacogenetic studies in COPD have been limited to candidate gene studies based on predetermined clinical trial end points. These usually include changes in FEV₁ or exacerbation frequency in response to therapies, mostly β -agonists. Pharmacogenetic studies have the potential to develop biomarkers that would identify the most appropriate current or future therapies for individuals with COPD.

β_2 -ADRENERGIC RECEPTOR PHARMACOGENETICS

The majority of pharmacogenetic studies focus on the bronchodilator response to SABA for two reasons: First, SABA therapy is the most prescribed treatment for the management of COPD, and second, acute bronchodilator response to SABA is a simple measurement.² One of the earliest pharmacogenetic studies for SABA was a linkage analysis of the BEOCOPD cohort, which estimated a heritability of 10% and 26% for acute bronchodilator responsiveness.³⁴²

The most intensively studied locus for β_2 -adrenergic receptor agonist bronchodilator response has focused on

variation in *ADRB2*. Multiple candidate gene studies have evaluated the role of Gly¹⁶Arg and other variants (including Gln²⁷Glu) at the *ADRB2* locus in determining lung function responses to SABA. These studies have reported conflicting results that favor the absence of a genotypic effect for any single variant. For example, two noncoding *ADRB2* SNPs were associated with albuterol bronchodilator response in the NETT cohort but not replicated in the BEOCOPD cohort (which consisted of probands with early-onset COPD and, for the most part, unaffected family members). In addition, haplotypes of two coding SNPs in *ADRB2* (Gly¹⁶Arg and Gln²⁷Glu) were associated with bronchodilator responsiveness in the NETT cohort but not in BEOCOPD subjects.³⁴³ Gly¹⁶Arg and Arg¹⁶Gln²⁷ genotypes were also associated with acute bronchodilator response to albuterol in Japanese subjects with COPD; this association was not observed in other studies of *ADRB2* in Japanese subjects with COPD.^{344,345} In the latter Japanese study, Gly¹⁶Arg was associated with preferential response to either the short-acting muscarinic receptor antagonist oxytropium or the SABA albuterol.³⁴⁴

Additional genes outside of *ADRB2* and the β_2 -adrenergic receptor pathway have been evaluated as potential loci for lung function responses to acute SABA therapy through candidate gene studies. A study of different biologic COPD candidate genes in the NETT cohort identified three SNPs in *EPHX1* and three SNPs in *SERPINE2* associated with the bronchodilator response to albuterol. Of these, one SNP in *EPHX1* was replicated in the BEOCOPD cohort.³⁴³

Long-acting bronchodilators such as LABA and LAMA are among the most effective and commonly used long-term therapies for COPD and have been evaluated by different pharmacogenetic association studies, most of which have focused on variation in *ADRB2*. Among the first pharmacogenetic studies for LABA in COPD was an analysis of the Korean Obstructive Lung Disease cohort treated with a LABA, salmeterol, and an ICS, fluticasone, for 12 weeks. LABA and ICS treatment resulted in improvements in lung function, independent of *ADRB2* genotype.³⁴⁶ Gene variation at the Gly¹⁶Arg locus was also not associated with changes in lung function or exacerbation frequency in response to LABA in two large independent COPD studies in the United States, which randomized subjects to treatment with the LABA, formoterol, with or without an ICS, budesonide.³⁴⁷ Similar to pharmacogenetic studies in asthma, variation at the *ADRB2* locus does not appear to impact therapeutic responses to LABA therapy in COPD.

The muscarinic acetylcholine receptor is a G protein-coupled receptor that activates phospholipase C and protein kinase A, leading to increased airway smooth muscle contractility.³⁴⁸ The muscarinic receptor subtype M₃ is implicated in airway smooth muscle contractility in COPD and is the target for inhaled LAMA therapy.^{349,350} In addition, the M₃ receptor has been shown to phosphorylate the β_2 -adrenergic receptor and the G_s subunit, resulting in the β_2 -adrenergic receptor desensitization.³⁵¹ The intracellular signaling cross-talk between the two G protein-coupled receptor signal transduction pathways regulated by the muscarinic receptor and the β_2 -adrenergic receptor provides the rationale for the study of *ADRB2* polymorphisms in COPD cohorts treated with LAMA therapy.

Some pharmacogenetic studies have evaluated variants at the *ADRB2* locus in COPD clinical trial cohorts where subjects were randomized to LABA or LAMA therapy. A candidate gene study of COPD subjects randomized to tiotropium for 8 weeks demonstrated that Arg¹⁶ homozygotes experienced greater improvements in FEV₁ and symptom control during tiotropium treatment than did Gly¹⁶Arg heterozygotes and Gly¹⁶ homozygotes.³⁵² A larger study of COPD subjects randomized to salmeterol or tiotropium for 1 year demonstrated that salmeterol was more effective in preventing COPD exacerbations in Arg¹⁶ homozygotes than in those with the remaining Gly¹⁶Arg genotypes, perhaps implying effects of different variants in LD with this locus.^{353,354}

Pharmacogenetic studies in COPD remain limited to candidate gene studies in clinical trial cohorts. Future pharmacogenetic studies should be performed using GWAS, independent large clinical trial cohorts, or genotype-stratified trials to replicate known pharmacogenetic loci and identify novel gene pathways that either act independently or through additive effects on therapeutic responses to inhaled β -agonists, LAMA, and ICS therapies. Just as for asthma, pharmacogenetic studies in COPD have the potential to identify genetic markers that could be used to characterize subgroups of nonresponders, responders, or a subgroup at risk for adverse responses, which will facilitate the development of precise combination therapies.

EPIGENETICS AND RARE GENE VARIATION IN ASTHMA AND COPD

Epigenetic regulation is mediated by gene modifications that alter transcription without a change in the DNA sequence. Environmental exposures may trigger epigenetic modifications and, therefore, contribute to asthma or COPD pathogenesis in ways that are not detectable using traditional genetic approaches. *Rare genetic variants*, which have allele frequencies of less than 1% to 5%, are not genotyped in GWAS, which were designed to tag genomic regions with common SNPs. Rare variants have the potential to exhibit strong effects on phenotype similar to what happens in single gene diseases such as cystic fibrosis.

EPIGENETICS IN ASTHMA AND COPD

Epigenetic regulation can be mediated through DNA methylation, histone acetylation, or chromatin condensation at gene promoters, which alter gene transcription without changes in the DNA code. DNA methylation is mediated by enzymes (DNA methyltransferases) that transfer a methyl group to cytosine at position 5. Methylation of DNA at regulatory regions such as gene promoters results in enhanced binding of methyl-cytosine binding proteins and *histone deacetylases* (HDACs) to repress gene transcription. HDACs are nuclear enzymes that deacetylate core histones, resulting in chromatin condensation that blocks the binding of transcription factors and RNA polymerase to gene promoters, thus repressing gene transcription. Histone acetyltransferases are nuclear enzymes that acetylate core

histone, resulting in chromatin relaxation, which enhances gene transcription.³⁵⁵

In COPD, HDACs have been shown to be critical to the epigenetic regulation of different proinflammatory cytokines in alveolar macrophages. In alveolar macrophages, treatment with the glucocorticoid dexamethasone resulted in recruitment of HDAC2 to the *granulocyte-macrophage colony stimulating factor* (GM-CSF) promoter region and inhibition of histone acetyltransferases. These epigenetic modifications blocked histone H4 acetylation at the GM-CSF promoter, resulting in repression of IL-1 β -stimulated GM-CSF transcription, an anti-inflammatory effect in response to glucocorticoid treatment.³⁵⁶ The epigenetic regulation of airway inflammation through histone acetylation and its impact on COPD severity was evaluated in surgically resected lung tissue specimens from subjects with COPD of varying severity and nonsmoker controls without COPD. Expression of *HDAC2*, *HDAC5*, and *HDAC8* was lower in lung tissue from COPD subjects than in nonsmoking controls, while total HDAC activity was significantly lower in those with COPD. In addition, HDAC activity directly correlated with FEV₁ and FEV₁/FVC, and inversely correlated with histone H4 acetylation and IL-8 mRNA expression in all subjects and those with COPD.³⁵⁷ The role of HDACs as an important epigenetic factor for COPD pathogenesis was subsequently demonstrated in a large-scale meta-analysis GWAS of more than 48,000 non-Hispanic white subjects from the SpiroMeta and CHARGE consortia and an independent replication cohort of more than 46,000, which identified *HDAC4* on chromosome 2q37 as a locus for lung function in the general population.²⁸⁹

The *ADAM33* promoter has variable methylation at CpG-rich regions (cytosine next to a guanine) or CpG islands resulting in gene hypermethylation or silencing in epithelial cells and hypomethylation or increased expression in fibroblasts.³⁵⁸ In addition, transforming growth factor- β stimulation reduces *ADAM33* mRNA expression in fibroblasts through histone methylation and deacetylation, which results in chromatin condensation at the *ADAM33* promoter and reduced gene transcription.³⁵⁹ Epigenetic mechanisms appear to regulate *ADAM33* expression; however, case-control studies have failed to show differences in *ADAM33* methylation between asthmatic and control subjects.³⁶⁰ Whole-genome epigenetic studies have been performed in small asthma cohorts; larger studies are needed in well-characterized cohorts to identify novel epigenetic mechanisms through which specific environmental exposures contribute to the heritability of asthma and COPD.^{361,362}

RARE VARIANTS IN ASTHMA AND COPD

The analysis of common variants in asthma and COPD was initially based on the common variant–common disease hypothesis that multiple common variants with weak to modest effect determine disease susceptibility and severity. Nearly all genetic studies in asthma and COPD analyzed common SNPs from the individual gene to the whole-genome level. Common SNPs were critical for the creation of cost-effective genome-wide genotyping panels for GWAS in large human populations and have been able to scan entire genomes based on LD with other variants and, thus,

the tagging of haplotype blocks. GWAS have only investigated discoveries based on common variant associations; however, rare variants have become increasingly recognized as potential loci for disease susceptibility.

Next-generation, whole-genome sequencing has the potential to identify rare variants, including SNPs and polynucleotide insertions and deletions, which are not evaluated in a GWAS. The 1000 Genomes Project Consortium used whole-genome sequencing technology to map human variation by sequencing 1097 individual genomes from 14 different populations drawn from Europe, East Asia, sub-Saharan Africa, and the Americas. The 1000 Genomes Project investigators reported an enrichment of rare variants with an allele frequency less than 0.005 in subjects from all populations, likely due to a recent explosion in population size.^{363,364} Populations from an African ancestry had three times as many rare variants with an allele frequency less than 0.05 than did those of European and Asian origin, reflecting ancestral bottlenecks in the latter, non-African populations.^{364,365} The investigators also reported that each individual had at least 240 rare coding variants (allele frequency less than 0.05) and hundreds of noncoding variants at conserved motifs such as transcription factor binding sites.³⁶⁴

Based on the high frequency of potentially functional rare variants, it became evident that rare functional variants might play a role in disease pathogenesis. The analysis of rare variants in human disease is based on the rare variant–common disease hypothesis that rare variants with strong effects on phenotype have major effects on disease risk. Rare variants were initially analyzed by collapsing variants within an individual gene to overcome the statistical challenge of small sample sizes; however, newer methods have been developed that account for the directionality of individual rare variants.^{142,366–374}

The number of studies analyzing rare variants in asthma and COPD is small but informative and provides preliminary evidence that justifies further study. Torgerson and coworkers³⁶⁹ analyzed rare variants in 53 asthma candidate genes from 450 asthma subjects and 515 controls from Childhood Asthma Research and Education Network, SARP, CSGA, and the Genomic Research on Asthma in the African Diaspora cohorts. C-alpha testing for gene-level rare variant associations identified significant rare variant associations with asthma susceptibility for rare coding variants in *DPP10* for African Americans and *IL12RB1* for non-Hispanic whites.³⁶⁹ This study provided the first evidence for the role of rare variants in asthma susceptibility; to date, there has not been a whole-genome association study of rare variants for asthma susceptibility loci.

ADRB2 has a rare coding variant, Thr¹⁶⁴Ile, which has been associated with reduced baseline lung function and baseline airflow obstruction ($FEV_1/FVC < 0.7$) in a cross-sectional analysis of more than 62,000 subjects from the Copenhagen General Population Study and the Copenhagen City Heart Study including a subset of 1300 patients with self-reported asthma.²¹¹ Thr¹⁶⁴Ile is located within the fourth transmembrane domain of the β_2 -adrenergic receptor and is associated with impaired receptor ligand binding affinity and coupling to G_s protein in response to different SABAs and LABAs, as well as decreased binding of salmeterol to the “salmeterol exosite.”^{209,210} Thr¹⁶⁴Ile has been

implicated as a locus for baseline lung function and potentially COPD in this population-based cohort; this rare variant also has the potential to contribute to uncommon, life-threatening adverse responses to inhaled β -agonists as discussed previously.²¹²

Our understanding of the role of rare variants in asthma and COPD susceptibility and severity will be further studied as more genomes from different racial groups are sequenced and as statistical methodologies are developed to analyze this ever expanding volume of genetic data.

GENETICS OF ASTHMA AND COPD: LESSONS LEARNED AFTER 20 YEARS OF EXPERIENCE

Research on the genetics of asthma and COPD over the past 20 years has demonstrated that variation in multiple genes from interacting pathways contributes to disease susceptibility, disease severity, and the response to different therapeutic agents. Earlier family-based studies provided the first clues about the polygenic nature of these obstructive airway diseases. Subsequent, biologic candidate gene studies and larger GWAS resulted in discoveries demonstrating important susceptibility or disease-modifying loci, which have added to our understanding of the complex genetics underlying asthma and COPD. Within each disease, there are common biologic gene pathways. In asthma, these genes primarily regulate proinflammatory pathways, the response to epithelial injury, and lung development. In COPD, these genes regulate nicotine addiction, lung development, proinflammatory pathways, and the antioxidant pathways. Some genes are common to both asthma and COPD as loci for susceptibility or disease severity and include genes that regulate lung development and the IL-6 inflammatory pathway.

The past 20 years have witnessed the mapping of the human genome, the development of high-throughput genotyping for GWAS, and, more recently, the completion of the 1000 Genomes Project through next-generation sequencing. Despite these accomplishments, many of the scientific discoveries stemming from these advances have not completely explained the heritability for asthma and COPD. In GWAS, some of this stems from the need to evaluate very large population cohorts in which comprehensive phenotyping is not practical. Thus, disease heterogeneity and subphenotypes are not adequately investigated, thereby reducing the ability of genetic approaches to characterize pathogenetic disease mechanisms. In addition, unlike single-gene mendelian diseases, such as cystic fibrosis, multiple genetic loci need to be interrogated to determine genetic profiles that predict disease susceptibility and progression. These same issues are true for most diseases, including cardiovascular, metabolic, and neoplastic disorders. Future genomic approaches will continue to focus on larger populations using unbiased, genome-wide approaches to identify novel genetic loci of disease susceptibility, disease severity, and therapeutic responses. Continued evaluation of new discoveries in the context of previously known loci will facilitate the identification of gene-gene interactions and the critical additive effects

of multiple genes that will serve to predict disease susceptibility, risk for progression of severity, and have the potential of leading to the development of novel therapies.

Next-generation DNA sequencing is based on massively parallel sequencing technologies that will allow for high-throughput whole-genome and whole-exome sequencing with the potential to identify rare variants, polynucleotide insertion-deletions, duplications, and epigenetic modifications, which are not captured by current SNP-based panels, thus further capturing hereditary factors in asthma and COPD. The challenge for these whole-genome sequencing approaches will be the extensive bioinformatics resources required. Larger-scale genotyping platforms covering 2 million or more SNPs can now be developed based on whole-genome sequence mapping data from different racial groups, thus allowing for cost-effective, comprehensive genotyping in admixed populations. As the costs associated with comprehensive genotyping and DNA sequencing decline and our understanding of the genetics of asthma and COPD improves, it will then be possible to create biomarker panels designed for precise approaches in medicine.⁴ Before genomics research can be applied to precise, personalized medicine, it will be necessary to continue adapting to the analysis of the exponentially increasing volumes of genetic data to identify and replicate associations in larger, comprehensively characterized human cohorts with a combination of analytic methods and in vitro functional studies.

Key Points

- Genetic variation has major effects on asthma and COPD susceptibility due to the action of many different genes that are polymorphic (contain gene variants or polymorphisms) or undergo epigenetic regulation (changes in gene expression without changes in the genetic code, e.g., gene methylation).
- Multiple potential environmental exposures interact with risk or severity genes for the *development* or *progression* of asthma and COPD, whereas cigarette smoke exposure is the primary environmental factor for the development of COPD and emphysema.
- Family-based studies provided the first clues about the polygenic nature of asthma and COPD; subsequent, biologic candidate gene studies and larger *genome-wide association studies* (GWAS) have resulted in discoveries of important susceptibility and disease-modifying loci.
- These genetic studies have identified common biologic gene pathways that regulate proinflammatory pathways, responses to epithelial injury, and lung development important in determining asthma susceptibility and severity; gene pathways that regulate nicotine addiction, lung development, proinflammatory pathways, and the antioxidant pathways are important in COPD.
- Variation in genes within these pathways have been identified as genetic factors for disease susceptibility, progression, and severity in both asthma and COPD, thus demonstrating overlapping biologic mechanisms in these obstructive airway diseases.
- Pharmacogenetics examines the role of gene variation in therapeutic responses to pharmacologic therapies.

In asthma and COPD, most pharmacogenetic studies have evaluated biologic candidate genes with few GWAS performed for inhaled glucocorticoid and short-acting β -agonist bronchodilator response in asthma.

- The discoveries that have stemmed from linkage studies, biologic candidate gene studies, and GWAS have not completely explained the heritability for asthma and COPD, likely because of the need to evaluate larger well-characterized populations, the role of gene-by-environment interactions (epigenetic regulation), and the potential strong effects of rare genetic variants on phenotype, which have not been evaluated by GWAS.
- Unlike single-gene mendelian diseases, such as cystic fibrosis, multiple genetic loci need to be interrogated to determine genetic profiles that predict disease susceptibility and progression in asthma and COPD. Precise medicine is becoming a realistic goal because of the large volume of genetic and phenotype data now being collected with next-generation DNA sequencing, increasingly comprehensive whole-genome genotyping chips, and larger, well-characterized study cohorts with these obstructive airway diseases.

FEDERAL REGULATION OF TOBACCO ELECTRONIC CIGARETTES

INTRODUCTION

Cigarette smoking remains the leading cause of preventable premature morbidity and mortality in the United States and in many countries around the world. An average of 443,000 people in the United States die prematurely from tobacco-related disease in a year, which includes one of every three cancers and one in five overall deaths.¹ A lifelong smoker has about a one in three chance of dying prematurely from a complication of smoking.² Life expectancy is shortened by more than 10 years among current smokers.³ The increased risk for death from smoking is now equal between men and women in the United States,⁴ and the World Health Organization has estimated that more than a billion deaths in the 21st century will be attributed to tobacco consumption.

Smoking is particularly relevant to respiratory medicine, because it is by far the major cause of lung cancer and *chronic obstructive pulmonary disease* (COPD) in developed countries. Smoking is also a substantial causative factor in respiratory infections, including pneumococcal pneumonia, influenza, and tuberculosis.

EPIDEMIOLOGY OF CIGARETTE SMOKING

Currently about 42.1 million individuals (18.1% of the adult population) in the United States are cigarette smokers, including 20.5% of men and 15.8% of women.¹ The percentage who smoked 30 or more cigarettes per day declined significantly, from 12.6% in 2005 to 9.1% in 2011, and the proportion of those who smoked 1 to 9 cigarettes per day increased from 16.4% to 22.0%. In the United States an increasing number of smokers (as many as 25% in some areas) are nondaily smokers. People who are less well educated and/or have unskilled occupations are more likely to smoke. For example, 33.8% of people with 9 to 11 grades of education are smokers, compared to 9.9% of those with a college degree. High rates are seen in those living below

the federal poverty level (27.7%), those 18 to 24 years of age (23.8%), and those in construction and extraction industries (30%).⁵

There are more than 1 billion smokers worldwide, the majority of whom live in low- and middle-income countries.⁶ Cigarette smoking and exposure to secondhand smoke together are responsible for about 6.3 million annual deaths worldwide and 6.3% of the global burden of disease. The World Health Organization Framework Convention on Tobacco Control aims to reduce both the demand and the supply of tobacco around the world through educational, political, and legislative means.⁷

TOXICOLOGY OF CIGARETTE SMOKE

Tobacco smoke is an aerosol of droplets (particulates) containing water, nicotine and other alkaloids, and tar. Tobacco smoke contains several thousand different chemicals, many of which may contribute to human disease.⁸ Major toxic chemicals in the particulate phase of tobacco include nicotine, benzo(a)pyrene and other polycyclic hydrocarbons, *N*'-nitrosonornicotine, β -naphthylamine, polonium-210, nickel, cadmium, arsenic, and lead. The gaseous phase contains carbon monoxide, acetaldehyde, acetone, methanol, nitrogen oxides, hydrogen cyanide, acrolein, ammonia, benzene, formaldehyde, nitrosamines, and vinyl chloride. Tobacco smoke may produce illness by way of systemic absorption of toxins and/or cause local pulmonary injury by oxidant chemicals.

SMOKING-RELATED DISEASES

Tobacco use is a major cause of death from cancer, cardiovascular disease, and pulmonary disease (Table 46-1). Smoking is also a major risk factor for osteoporosis, reproductive disorders, and fire-related and trauma-related injuries.

Table 46-1 Health Hazards of Tobacco Use (Risks Increased by Smoking)

CANCER (See Table 46-2)

CARDIOVASCULAR DISEASE

Sudden death
Acute myocardial infarction
Unstable angina
Stroke
Peripheral arterial occlusive disease (including thromboangiitis obliterans)
Aortic aneurysm

PULMONARY DISEASE

Lung cancer
Chronic bronchitis
Emphysema
Asthma
Increased susceptibility to pneumonia and to pulmonary tuberculosis
Increased susceptibility to desquamative interstitial pneumonitis
Increased morbidity from viral respiratory infection

GASTROINTESTINAL DISEASE

Peptic ulcer
Esophageal reflux

REPRODUCTIVE DISTURBANCES

Reduced fertility
Premature birth
Lower birth weight
Spontaneous abortion
Abruptio placentae
Premature rupture of membranes
Increased perinatal mortality

ORAL DISEASE (SMOKELESS TOBACCO)

Oral cancer
Leukoplakia
Gingivitis
Gingival recession
Tooth staining

OTHER

Non-insulin-dependent diabetes mellitus
Earlier menopause
Osteoporosis
Cataract
Tobacco amblyopia (loss of vision)
Age-related macular degeneration
Premature skin wrinkling
Aggravation of hypothyroidism
Altered drug metabolism or effects

CANCER

Smoking, the largest preventable cause of cancer (Table 46-2), is responsible for about 30% of cancer deaths.⁹ Many chemicals in tobacco smoke may contribute to carcinogenesis as tumor initiators, co-carcinogens, tumor promoters, or complete carcinogens.^{8,10} Complexes of tobacco smoke carcinogens and DNA are thought to be a crucial step in cancer induction.¹¹ Cigarette smoking induces specific patterns of p53 gene mutations that are associated with squamous cell carcinomas of the lung, head, and neck.¹² Lung cancer is the leading cause of cancer deaths in the United States and is predominantly attributable to cigarette smoking.⁴ The risk for lung and other cancers is proportional to the number of cigarettes smoked per day and even more strongly to the duration of smoking. In current smokers the levels of DNA adducts (covalently bound car-

cinogens) in nontumor lung tissue or blood mononuclear cells are related to cigarette consumption.¹³ Of note, however, in former smokers DNA adduct levels were inversely associated with age of initiation of smoking.¹⁴ This finding suggests that young smokers are more susceptible to DNA damage and persistence of genetic alterations than are those who begin smoking at an older age, which has substantial implications for the need to prevent adolescent smoking. A recent genome-wide association study analysis of a cohort of smokers compared to a cohort of never smokers has confirmed that the expression of thousands of genes is altered by cigarette exposure.¹⁵ Additional information from deep sequencing of a lung cancer tumor provides a picture of widespread genetic mutational change with hundreds of point somatic variants and multiple large structural genetic changes such as chromosomal segment deletion.¹⁶

Workplace exposure to asbestos or α -radiation (the latter in uranium miners) synergistically increases the risk for lung cancer in cigarette smokers.¹⁷ Alcohol use interacts synergistically with tobacco in causing oral, laryngeal, and esophageal cancer.¹⁸ The mechanism of interaction may involve alcohol solubilizing tobacco carcinogens and/or alcohol-related induction of liver or gastrointestinal enzymes that metabolize and activate tobacco carcinogens. Smoking is associated with 15% of leukemia cases in adults and 20% of colorectal cancers.^{19,20} Based on large cohort studies and a meta-analysis, cigarette smoking in women before having their first child is associated with increased breast cancer risk.²¹

A detailed description of the epidemiology and the pathogenesis of smoking-induced lung cancer is presented elsewhere in this textbook (see Chapters 51 and 52).

CHRONIC PULMONARY DISEASE

More than 80% of chronic obstructive lung disease in the United States is attributable to cigarette smoking. Cigarette

smoking also increases the risk for respiratory infection, including pneumonia, and results in greater disability from viral respiratory tract infections.^{22,23} Pulmonary disease from smoking includes the overlapping syndromes of chronic bronchitis (cough and mucus secretion), emphysema, and airway obstruction. The lung pathologic conditions produced by cigarette smoking include loss of cilia, mucous gland hyperplasia, increased number of goblet cells in the central airways, inflammation, goblet cell metaplasia, squamous metaplasia, mucus plugging of small airways, destruction of alveoli, and a reduced number of small arteries. The mechanism of injury is complex and seems to include inflammation as well as direct injury by oxidant chemicals, increased elastase activity (a protein that breaks down elastin and other connective tissue), and decreased antiprotease activity.²⁴ A genetic deficiency of α_1 -antiprotease activity produces a similar imbalance between pulmonary protease and antiprotease activity and is a risk factor for early and severe smoking-induced pulmonary disease.²⁵

In addition to the effects of cigarette smoke-induced injury, the delivery of carbon monoxide from cigarette smoke serves to worsen the level of functioning in smokers who have significant COPD. Carbon monoxide avidly binds to hemoglobin, reduces the capacity of hemoglobin to carry oxygen, and impairs oxygen release at the tissues. Thus carbon monoxide exposure produces a functional anemia. Carboxyhemoglobin levels are typically 5% to 10% in smokers, compared to 1% or less in nonsmokers. In a normal person, carbon monoxide from cigarette smoke causes few symptoms, but, in patients with pulmonary disease, carbon monoxide has the potential to cause significant impairment. Exposure to carbon monoxide at levels even less than that derived from cigarette smoking have been shown to reduce exercise tolerance in patients with COPD.

Cigarette smoking may contribute to the development of asthma, although this potential link could be confounded by the increased rate of pulmonary infections observed in smokers. A longitudinal study of 5800 individuals taking part in a British national study suggested that regular smoking was associated with asthma in people between the ages of 17 and 33 (*odds ratio* [OR] = 4.4).²⁶ The relationship between asthma and smoking was further studied in more than 14,000 Finnish adults, and the prevalence of asthma was higher among male smokers than among male nonsmokers (relative risk = 1.7), although no smoking effect was observed for women.²⁷ Current smokers, compared to never and ex-smokers, demonstrate higher asthma severity scores, more frequent asthma symptoms, and more frequent asthma attacks (OR = 2.4).²⁸ Silverman and coworkers²⁹ evaluated 1847 emergency department patients presenting with acute asthma and found that 35% of patients were current smokers. Half of these smoking asthmatics reported that cigarette use worsened their asthma symptoms.

The link between secondhand smoke and asthma would support the hypothesis that tobacco exposure worsens bronchial hyperresponsiveness. A study evaluating infants in their first year of life exposed to smoking mothers demonstrated they were 2.1 times more likely to develop asthma than children of nonsmoking mothers.³⁰ Likewise, the Swiss Study on Air Pollution and Lung Disease in Adults

suggested that secondhand smoke was associated with an increased risk for asthma (OR = 1.4) or reactive airway disease in nonsmoking adults.³¹

There are other links between smoking and inflammatory lung conditions such as asthma. In a small cohort of healthy nonasthmatic smokers, bronchoalveolar lavage fluid documented altered macrophage cytokine release, increased cellularity, and depressed levels of interleukin-6.³² These abnormalities would further suggest a plausible link between smoking and an increased incidence and severity of chronic lung inflammatory conditions.

Cigarette smoking has been associated with multiple non-neoplastic pulmonary disorders other than emphysema and chronic bronchitis. These include respiratory bronchiolitis-associated interstitial lung disease, desquamative interstitial pneumonitis, Langerhans cell histiocytosis, cryptogenic interstitial fibrosing alveolitis, and eosinophilic pneumonia.³³ Ninety percent of patients with pulmonary Langerhans cell histiocytosis are smokers. Respiratory bronchiolitis and desquamative interstitial pneumonitis have similar histopathologic features and are characterized by the accumulation of pigmented macrophages within the alveoli. Respiratory bronchiolitis ("smoker's bronchiolitis") is most often an asymptomatic finding that can persist after smoking cessation.³⁴ Desquamative interstitial pneumonitis often affects smokers in their fourth or fifth decade of life, and the symptoms are more frequent in smokers.³³ Smoking may also have an association with idiopathic pulmonary fibrosis.³⁵ Smoking is over-represented in patients with idiopathic pulmonary fibrosis compared to the general population, and the overall OR for smoking as a risk factor for idiopathic pulmonary fibrosis was 1.6.³⁶

INFECTION

Cigarette smoking is a major risk factor for respiratory tract and other systemic infections. Both active and passive cigarette smoke exposure increase the risk for infection.^{37,38} The mechanisms by which smoking increases risk are multifactorial and include structural and immunologic alterations. As mentioned previously, cigarette smoking causes structural changes in the respiratory tract. These changes include peribronchiolar inflammation and fibrosis, increased mucosal permeability, impairment of mucociliary clearance, changes in pathogen adherence, and disruption of the respiratory epithelium. A number of components of cigarette smoke, including acrolein, acetaldehyde, formaldehyde, free radicals produced from chemical reactions within the cigarette smoke, and nitric oxide, may contribute to the observed structural alterations in airway epithelial cells.

Immunologic mechanisms include alterations in cellular and humoral immune system function. These include a decreased level of circulating immunoglobulins, a depression of antibody response to certain antigens, a decrease in CD4⁺ lymphocyte counts, an increase in CD8⁺ lymphocyte counts, depressed phagocyte activity, and decreased release of proinflammatory cytokines. Many of the immunologic disturbances in smokers resolve within 6 weeks after smoking cessation, supporting the idea that smoking cessation is highly effective in a relatively short period of time in the prevention of infection.³⁷

Table 46-3 Cigarette Smoking and Infection

	Odds Ratio (95% CI)
Tuberculosis	4.5 (4.0–5.0)
Legionnaires' disease	3.5 (2.1–5.8)
HIV infection	3.4 (1.6–7.5)
Periodontal disease	2.8 (1.9–4.1)
Pneumococcal pneumonia	2.6 (1.9–3.5)
Meningococcal disease	2.4 (0.9–6.6)
Influenza	2.4 (1.5–3.8)
<i>Helicobacter pylori</i>	2.2 (1.2–4.0)
Common cold	1.5 (1.1–1.8)

CI, confidence interval; HIV, human immunodeficiency virus.

Cigarette smoking is associated with an increased risk for bacterial and viral infections (Table 46-3). Cigarette smoking is a substantial risk factor for pneumococcal pneumonia, especially in patients with COPD. Smoking is strongly associated with invasive pneumococcal disease in otherwise healthy adults.²³ A population-based case control study showed smoking was the strongest independent risk factor for invasive pneumococcal disease among immunocompetent adults. The OR was 4.1 (95% confidence interval [CI], 2.4 to 7.3) for active smoking and 2.5 (95% CI, 1.2 to 5.1) for passive smoke exposure in nonsmokers compared to nonexposed nonsmokers. The attributable risk in this population was 51% for cigarette smoking and 17% for passive smoking, and this effect showed a strong dose response. The risk for pneumococcal disease declined to nonsmoker levels 10 years after cessation. Cigarette smoking has also been shown to be associated with a nearly twofold increased risk for community-acquired pneumonia, with 32% of the risk attributable to cigarette smoking.³⁹

Cigarette smoking increases the risk for developing and the severity of viral infections, including the common cold, influenza, and varicella. Influenza infections are more severe, with more cough, acute and chronic phlegm production, breathlessness, and wheezing in smokers.²² Influenza infections produce more lost workdays in smokers compared to nonsmokers. Influenza vaccination is effective in preventing the disease in smokers, and smoking should be considered to be a high-priority indication for influenza vaccination. The role of development of varicella pneumonitis in adults is reported to be substantially greater in smokers compared to nonsmokers.⁴⁰

Tuberculosis is perhaps the most important smoking-associated infection. Cigarette smoking is a risk factor for tuberculin skin test reactivity, for skin test conversion, and for the development of active tuberculosis. A large case-control study from India examined smoking and tuberculosis in men between 35 and 69 years of age. The tuberculosis prevalence relative risk was 2.9 (95% CI, 2.6 to 3.3) for ever smokers compared to never smokers, and the prevalence was higher with a higher level of cigarette consumption.⁴¹ The mortality from tuberculosis among men 25 to 69 years old showed a relative risk of 4.5 (95% CI, 4.0 to 5.0) and 4.2 (95% CI, 3.7 to 4.8) for urban and rural residents, respectively. The authors found that the proportion of deaths from tuberculosis attributable to smoking was 61% greater than the proportion of deaths from vas-

cular disease or cancer attributable to smoking. Thus it is likely that smoking contributes substantially to the worldwide disease burden of tuberculosis.⁴²

Of historical interest is the relationship between tuberculosis and the risk for cigarette smoking in the early 20th century. Before that time, chewing tobacco was the preferred type of tobacco. Public fear that users of chewing tobacco who spit in public places might be spreading tuberculosis is one of the factors that led to the increase in cigarette sales in the United States. This is nicely described by Kluger as follows: "Chewing tobacco was no longer merely messy but socially disagreeable in more crowded urban America, and in its inevitable byproduct, spitting, was now identified as a spreader of tuberculosis and other contagions and, thus, an official health menace. The leisurely pipe all at once seemed a remnant of a slower-tempo age, and cigar fumes were newly offensive amid thronged city life. The cigarette by contrast, could be quickly consumed and easily snuffed out on the job as well as to and from work."⁴³

CARDIOVASCULAR DISEASE

Although not the focus of this textbook, cardiovascular disease is common in patients with respiratory disease. This relates to the facts that both diseases are common and both increase with age and that smoking is a major risk factor for both respiratory disease and cardiovascular disease.

Cigarette smoking accounts for about 20% of cardiovascular deaths in the United States. Risks are increased for coronary artery disease, sudden death, cerebrovascular disease, and peripheral vascular disease, including aortic aneurysm.^{8,44} Cigarette smoking accelerates atherosclerosis and promotes acute ischemic events. The mechanisms of the effects of cigarette smoking are not fully elucidated but are believed to include (1) hemodynamic stress (nicotine increases the heart rate and transiently increases blood pressure); (2) endothelial injury and dysfunction (nitric oxide release and resultant vasodilation are impaired); (3) development of an atherogenic lipid profile (smokers have on average higher low-density lipoprotein levels, more oxidized low-density lipoprotein, and lower high-density lipoprotein cholesterol than nonsmokers do); (4) enhanced coagulability; (5) arrhythmogenesis; and (6) relative hypoxemia because of the effects of carbon monoxide.⁴⁵ As mentioned, carbon monoxide reduces the capacity of hemoglobin to carry oxygen and impairs the release of oxygen from hemoglobin to body tissues, both of which combine to result in a state of relative "anemia." As a compensation for the reduced oxygen-carrying capacity, polycythemia develops in smokers, with hematocrits often 50% or more. The polycythemia and the increased fibrinogen levels that are found in cigarette smokers also increase blood viscosity, which adds to the risk for thrombotic events. Cigarette smoking also induces a chronic inflammatory state, as evidenced by increased neutrophil count and increased levels of fibrinogen and C-reactive protein in the blood of smokers. Chronic inflammation is thought to contribute to atherogenesis.

Cigarette smoking acts synergistically with other cardiac risk factors to increase the risk for atherogenesis, plaque rupture, and acute ischemic events. Although the risk for cardiovascular disease is roughly proportional to cigarette consumption, the risk persists even at low levels of smoking,

that is, at one to two cigarettes per day.⁴⁶ Cigarette smoking reduces exercise tolerance in patients with angina pectoris and with intermittent claudication; in smokers, vasospastic angina is more common and the response to vasodilator medication is impaired. Smoking substantially increases the number and total duration of ischemic episodes as assessed by ambulatory electrocardiographic monitoring in patients with coronary heart disease.⁴⁷ The increase in relative risk for coronary heart disease because of cigarette smoking is greatest in young adults, who, in the absence of cigarette smoking, would have a relatively low risk.⁴⁴ Women who use oral contraceptives and smoke cigarettes have a synergistically increased risk for both myocardial infarction and stroke. Data suggest that implementing smoking bans at the community level has an appreciable impact on lowering hospital admission rates for coronary artery disease.^{48,49}

After acute myocardial infarction, persistent smokers have an increased risk for recurrent myocardial infarction and half the expected survival over the next 12 years compared to quitters.⁵⁰ Smoking also interferes with revascularization therapy for acute myocardial infarction. After thrombolysis, persistent smokers suffer a fourfold increased reocclusion rate than those who quit.⁵¹ Smokers also have an increased risk for reocclusion of a coronary artery after angioplasty or of occlusion of a bypass graft.⁵² Cigarette smoking is not a risk factor for hypertension per se but does increase the risk for complications, including the development of nephrosclerosis and progression to malignant hypertension.⁵³ Cigarette smoking has been shown to be a substantial contributor to morbidity and mortality in patients with left ventricular dysfunction. The mortality benefit of stopping smoking in such patients is equal to or greater than the benefit of therapy with angiotensin-converting enzyme inhibitors, β -blockers, or spironolactone.⁵⁴

WOUND HEALING/POSTOPERATIVE COMPLICATIONS

Cigarette smoking is associated with adverse postoperative events and delayed wound healing.⁵⁵ Postoperative complications can be tied to impaired clearance of secretions, altered immune function, and altered collagen synthesis, as well as the influence of underlying tobacco-related diseases (e.g., COPD and altered cardiovascular function). The mechanisms that can delay wound healing include cutaneous vasoconstriction (reducing skin blood flow), local thrombosis, and reduced oxygen-carrying capacity.

Smoking cessation substantially reduces postoperative complications. Moller and colleagues⁵⁶ published the results of a randomized, controlled trial of smokers awaiting elective hip or knee surgery at three hospitals in Copenhagen. They compared 56 patients in a smoking cessation intervention arm (83% stopped or reduced smoking) to 62 patients in a usual care arm targeting cessation 6 to 8 weeks before surgery. The overall complication rate was 18% in the smoking cessation arm and 52% in the controls, a highly significant difference. The greatest differences were seen in wound complication rates (5% versus 31%) and cardiovascular complications (0% versus 2%), without a significant difference in length of hospital stay.

A study of 489 adult patients undergoing ambulatory surgery demonstrated a significantly higher rate of respiratory complications in smokers compared to nonsmokers (32.8% in smokers versus 25.9% in nonsmokers) and wound infections (3.6% in smokers versus 0.6% in nonsmokers).⁵⁷ Causes of major pulmonary events after pneumonectomy for lung surgery were sought in a retrospective analysis of 261 patients.⁵⁸ Patients who continued to smoke within 1 month of operation were determined to be at an increased risk for pulmonary events, which was associated with increased postoperative mortality. Cigarette smoking is associated with an increased risk for hepatic artery thrombosis after liver transplantation, and cessation 2 years before transplantation was associated with a decreased risk.⁵⁹ Similar data exist regarding renal transplantation and allograft survival in smokers compared to nonsmokers.⁶⁰

The optimal window for smoking cessation intervention may be at 8 weeks before elective surgery, as suggested by data demonstrating that patients who had stopped smoking at least 2 months preoperatively had nearly maximal reduction in postoperative respiratory complications.⁶¹ A meta-analysis found that smoking cessation reduced postoperative complications by 41% and that each week of cessation increased the magnitude of benefit by 19%.⁶² An important issue related to elective surgery is that patients are often highly motivated to quit smoking just before elective surgery and can benefit from cessation counseling before surgery as well as in-hospital cessation counseling and medication in the postoperative setting. Specific issues related to smoking cessation are discussed later in this chapter.

OTHER COMPLICATIONS OF CIGARETTE SMOKING

Cigarette smoking increases the risk for duodenal and gastric ulcers, delays the rate of ulcer healing, and increases the risk for relapse after ulcer treatment.⁶³ Smoking is also associated with esophageal reflux symptoms. Smoking produces ulcer disease by increasing acid secretion, reducing pancreatic bicarbonate secretion, impairing the gastric mucosal barrier (related to decreased gastric mucosal blood flow and/or inhibition of prostaglandin synthesis), reducing pyloric sphincter tone, and increasing the risk for *Helicobacter pylori* infection.^{64,64a} Cigarette smoking is an independent risk factor for the development of non-insulin-dependent diabetes mellitus, which is a consequence of development of resistance to the effects of insulin.⁶⁵ The effects of nicotine seem to contribute at least in part to insulin resistance, and insulin resistance has been described in users of smokeless tobacco, who are not exposed to tobacco combustion products.

Cigarette smoking increases the risk for osteoporosis by reducing the peak bone mass attained in early adulthood and increasing the rate of bone loss in later adulthood. Smoking antagonizes the protective effect of estrogen replacement therapy on the risk for osteoporosis in postmenopausal women.⁶⁶ Cigarette smoking is a major cause of reproductive problems and results in approximately 4600 U.S. infant deaths annually. Growth retardation from cigarette smoking has been termed "fetal tobacco syndrome." Cigarette smoking causes reproductive

Table 46-4 Interaction Between Cigarette Smoking and Drugs

Drugs	Interaction (Effects Compared with Nonsmokers)	Significance
Antipyrine Caffeine Chlorpromazine Clozapine Desmethyldiazepam Estradiol Estrone Flecainide Fluvoxamine Haloperidol Imipramine Lidocaine Olanzapine Oxazepam Pentazocine Phenacetin Phenylbutazone Propranolol Tacrine Theophylline	Accelerated metabolism	May require higher doses in smokers, reduced doses after quitting
Oral contraceptives	Enhanced thrombosis, increased risk for stroke and myocardial infarction	Do not prescribe to smokers, especially if >35 years old
Cimetidine and other H ₂ -blockers	Lower rate of ulcer healing, higher ulcer recurrence rates	Consider using mucosal protective agents
Propranolol	Less antihypertensive effect, less antianginal efficacy; more effective in reducing mortality after myocardial infarction	Consider the use of cardioselective β-blockers
Nifedipine (and probably other calcium blockers)	Less antianginal effect	May require higher doses and/or multiple-drug antianginal therapy
Diazepam, chlordiazepoxide (and possibly other sedative-hypnotics)	Less sedation	Smokers may need higher doses
Chlorpromazine (and possibly other neuroleptics)	Less sedation, possibly reduced efficacy	Smokers may need higher doses
Propoxyphene	Reduced analgesia	Smokers may need higher doses

H₂, histamine₂.

complications by causing placental ischemia mediated by the hypoxic effects of chronic carbon monoxide exposure, endothelial dysfunction, and the general increase in coagulability produced by oxidant chemicals in cigarette smoke.⁶⁷

Other adverse effects of cigarette smoking include premature facial wrinkling, an increased risk for cataracts, age-related macular degeneration, olfactory dysfunction, and fire-related injuries. The last mentioned contributes significantly to the economic costs of tobacco use. Smoking reduces the secretion of thyroid hormone in women with subclinical hypothyroidism and increases the severity of clinical symptoms of hypothyroidism in women with subclinical or overt hypothyroidism, the latter effect reflecting antagonism of thyroid hormone action.⁶⁸ Cigarette smoking also potentially interacts with a variety of drugs by accelerating drug metabolism or by the antagonistic pharmacologic actions that nicotine and/or other constituents of tobacco have with other drugs (Table 46-4).

HEALTH HAZARDS OF SECONDHAND SMOKE

Considerable evidence indicates that exposure to secondhand smoke is harmful to the health of nonsmokers (Table

Table 46-5 Health Hazards of Secondhand Smoke in Nonsmokers

Children	Adults
Hospitalization for respiratory tract infection in first year of life	Lung cancer
Wheezing	Myocardial infarction
Middle ear effusion	Reduced pulmonary function
Asthma	Irritation of eyes, nasal congestion, headache
Sudden infant death syndrome	Cough

46-5). The U.S. Environmental Protection Agency classifies secondhand smoke as a class A carcinogen, which means that it has been shown to cause cancer in humans.⁶⁹

Secondhand smoke, also known as environmental tobacco smoke, consists of sidestream smoke that is generated while the cigarette is smoldering and mainstream smoke that has been exhaled by the smoker. Of the total combustion product from a cigarette, 75% or more enters the air. The constituents of secondhand smoke are qualitatively similar to those of mainstream smoke. However, some toxins, such as ammonia, formaldehyde, and nitrosamines, are present in much higher concentrations in secondhand smoke than in mainstream smoke. The Environmental Protection Agency has estimated that secondhand smoke is responsible for approximately 3000 lung cancer deaths

annually in nonsmokers in the United States, is causally associated with 150,000 to 300,000 cases of lower respiratory tract infection in infants and young children up to 18 months of age, and is causally associated with the aggravation of asthma in 200,000 to 1 million children.⁶⁹ Secondhand smoke exposure is also responsible for 40,000 cardiovascular deaths.⁷⁰ An appreciation of the hazards of secondhand smoke is important to the physician because it provides a basis for advising parents not to smoke when children are in the home, for insisting that child care facilities be smoke-free, and for recommending smoking restrictions in work sites and other public places.

NICOTINE ADDICTION

Tobacco use is motivated primarily by the desire for nicotine. Drug addiction is defined as compulsive use of a psychoactive substance, the consequences of which are detrimental to the individual or society. Understanding addiction is useful in providing effective smoking cessation therapy.⁷¹ Nicotine is absorbed rapidly from tobacco smoke into the pulmonary circulation; it then moves quickly to the brain, where it acts on nicotinic cholinergic receptors to produce its gratifying effects within 10 to 15 seconds after a puff. Smokeless tobacco is absorbed more slowly and results in less intense acute pharmacologic effects. With long-term use of tobacco, physical dependence develops, associated with an increased number of nicotinic cholinergic receptors in the brain. When tobacco is unavailable, even for only a few hours, withdrawal symptoms often develop, including anxiety, irritability, difficulty concentrating, restlessness, hunger, craving for tobacco, disturbed sleep, and, in some people, depression.

Addiction to tobacco is multifactorial, including a desire for the direct pharmacologic actions of nicotine, relief of withdrawal symptoms, and learned associations. Smokers report a variety of reasons for smoking, including pleasure, arousal, enhanced vigilance, improved performance, relief of anxiety or depression, reduced hunger, and control of body weight. Environmental cues—such as having a meal or a cup of coffee, talking on the phone, drinking an alcoholic beverage, or being with friends who smoke—often trigger an urge to smoke. Smoking and depression are strongly linked. Smokers are more likely to have a history of major depression than are nonsmokers. Smokers with a history of depression are also likely to be more highly dependent on nicotine and have a lower likelihood of quitting. When they do quit, depression is more apt to be a prominent withdrawal symptom.

Most tobacco use begins in childhood or adolescence.⁷² Risk factors for youth smoking include peer and parental influences; behavioral problems (e.g., poor school performance); personality characteristics such as rebelliousness or risk taking, depression, and anxiety; and genetic influences. The adolescent's desire to appear older and more sophisticated, such as emulating more mature role models, is another strong motivator. Environmental influences such as advertising and smoking in movies also contribute. Although smoking rates among adults have been declining since the 1970s, initiation rates for youth have remained constant since the mid-1980s. Approaches to preventing

tobacco addiction in youth include educational activities in schools, aggressive antitobacco media campaigns, taxation of tobacco products, changing the social and environmental norms (restricting indoor smoking, educating parents not to smoke around children), and deglamorizing smoking.

NEUROBIOLOGIC MECHANISMS OF ADDICTION

Nicotine binds stereoselectively to nicotinic cholinergic receptors in the brain, autonomic ganglia, the adrenal medulla, and neuromuscular junctions. Most relevant to nicotine addiction are the neuronal nicotinic cholinergic receptors. These are found throughout the brain, with the greatest number of binding sites in the cortex, thalamus, and interpeduncular nucleus, and substantial binding in the amygdala, septum, brain-stem motor nuclei, and locus coeruleus. The nicotinic cholinergic receptor is a ligand-gated ion channel, composed of five subunits. Most brain nicotinic cholinergic receptors are composed of α - and β -subunits. Usually there are two α - and three β -subunits, with the α -subunits responsible for ligand binding and the β -subunits mediating other aspects of receptor function.⁷³ There is much diversity of nicotinic cholinergic receptors with nine α -subunit isoforms (α_2 through α_{10}) and three β -subunit isoforms (β_2 through β_4) identified in brain tissues. Different nicotinic receptors are found in different parts of the brain and have different chemical conductances for sodium and calcium and different sensitivity to different nicotinic agonists. The different nicotinic receptors are believed to mediate different pharmacologic actions of nicotine, perhaps corresponding to the multiple effects of nicotine experienced by human smokers.⁷⁴

Nicotine receptors appear to be located both on cell bodies and at nerve terminals. All nicotine receptors are permeable to calcium ions. Nicotinic receptor activation works, at least in part and possibly in the main, by facilitating the release of neurotransmitters, including acetylcholine, norepinephrine, dopamine, serotonin, β -endorphin, gamma aminobutyric acid, and others.⁷⁵ Nicotine enhances fast excitatory synaptic transmission, which may contribute to learning and memory.^{76,77} Nicotine also releases growth hormone, prolactin, vasopressin, and adrenocorticotrophic hormone. The behavioral rewards from nicotine and perhaps nicotine addiction as well appear to be linked to dopamine release.⁷⁸

The two main dopamine systems in the brain are the mesocorticolimbic and the nigrostriatal systems. The mesocorticolimbic system includes the ventral tegmental area projecting to the nucleus accumbens, the cortex, and limbic regions. The nigrostriatal system includes the substantia nigra, pars compacta projecting to the dorsal striatum. Nicotine causes an increase in burst firing of ventral tegmental area neurons, resulting in release of dopamine in the nucleus accumbens.⁷⁸ Dopamine release is potentiated and sustained by nicotine-mediated release of glutamate.⁷⁹ Dopamine release in the outer shell of the nucleus accumbens is characteristic of the effects of many addicting drugs (e.g., heroin, cocaine, alcohol) and is thought to be an important site for drug-mediated reinforcement.⁸⁰

Whereas acute exposure to nicotine produces stimulation of dopaminergic neurons in mesolimbic pathways, chronic exposure to nicotine and other drugs of abuse produces other changes in mesolimbic function. Chronic

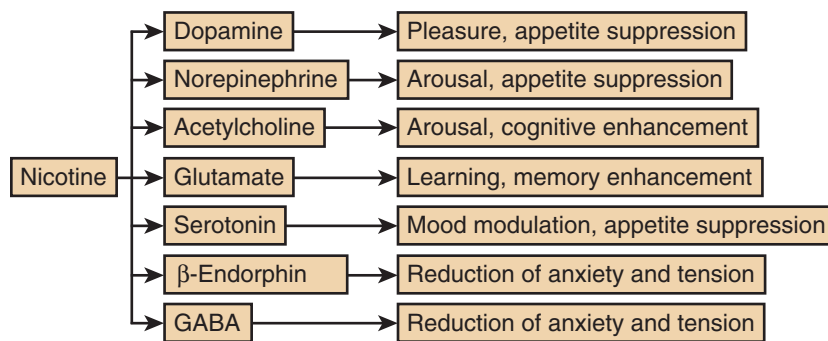

Figure 46-1 Neurochemical effects of nicotine. Nicotine leads to the release of many neurotransmitters, each of which may mediate specific aspects of nicotine addiction and reward. Dopamine release is believed to be the major link to behavioral rewards from nicotine. GABA, gamma aminobutyric acid.

nicotine exposure results in neuroadaptation or the development of tolerance, and the absence of nicotine results in subnormal release of dopamine and other neurotransmitters. Thus nicotine withdrawal may result in a state of deficient dopamine responses to novel stimuli in general and to a state of malaise and inability to experience pleasure. This has been termed “hedonic dysregulation” by Koob and LeMoal.⁸¹ Hedonic dysregulation may explain craving. The sensitivity to drug effects may explain why even a single slip might easily result in a return to compulsive drug use.

The release of various neurotransmitters discussed previously results in behavioral arousal, sympathetic neural activation, and a number of other effects that are believed to be rewarding. The release of specific neurotransmitters has been speculatively linked to the reported reinforcing effects of nicotine (Fig. 46-1). For example, enhanced release of dopamine and norepinephrine may be associated with pleasure as well as appetite suppression, the latter of which may contribute to lower body weight.⁸² Release of acetylcholine may be associated with improved performance on behavioral tasks and improvement of memory. Release of β -endorphin may be associated with reduction of anxiety and tension.

Although smokers give different explanations for their smoking, most agree that smoking produces arousal, particularly with the first cigarettes of the day, and relaxation, particularly in stressful situations. Consistent with reports of arousal, electroencephalographic desynchronization with an upward shift in the dominant alpha frequency and decreased total alpha and theta power follows cigarette smoking or the administration of nicotine.⁸³

LOW-YIELD CIGARETTES

It has been well demonstrated that smokers regulate their intake of nicotine. Smokers change the way they puff a cigarette depending on the nicotine yield as measured by the cigarette smoking machine.^{84,85} They puff lower-yield cigarettes more frequently or more intensely than higher-yield cigarettes, presumably to obtain more nicotine. Smokers who switch from higher-yield to lower-yield cigarettes consume more nicotine from the lower-yield cigarettes than is predicted by smoking machine tests. Conversely, smokers consume less nicotine than predicted from higher-yield cigarettes. The intake of nicotine, as measured using blood cotinine or nicotine concentrations or urine metabolites as markers of nicotine intake, has been studied in large groups of people smoking their own chosen

brand of cigarettes.⁸⁴ In such studies, nicotine intake correlates only weakly with the machine-determined yield. Despite smoking cigarettes with widely differing nicotine yields, smokers demonstrate only small differences in nicotine intake. Correspondingly, there is little or no health benefit of switching to lower- rather than higher-yield cigarettes.^{86,87}

The shift over the years from higher- to lower-yield cigarettes may explain the change in the pathologic characteristics of lung cancer.⁸⁸ That is, the percentage of lung cancers that are adenocarcinomas has increased, whereas the percentage of squamous cell cancers has decreased. The change in tumor type is believed to reflect the higher nitrosamine delivery of lower-yield cigarettes and the greater volume of inhalation of low-yield cigarettes that smokers adopt to compensate for lower level concentrations of nicotine in the smoke.

SMOKING CESSATION

Of cigarette smokers, 70% state they would like to quit and approximately 50% try to quit each year. Spontaneous quit rates are about 1% per year. Simple physician advice to quit increases the quit rate to 3%. Minimal intervention programs increase quit rates to 5% to 10%, whereas more intensive treatments, including smoking cessation clinics, can yield quit rates of 25% to 30%.⁸⁹

The main strategies for cessation are behavioral counseling, pharmacologic intervention, or a combination of the two. Many patients try over-the-counter smoking cessation medications before discussing smoking with their health care providers. The efficacy of over-the-counter medications may be limited by improper use of medications and concomitant untreated issues such as depression, alcoholism, or other factors. Assessing stress, exposure to family members or roommates who smoke, or other factors shown to predict relapse are an important part of history taking before a therapeutic intervention is undertaken.

GUIDELINES

Evidence-based guidelines for the treatment of tobacco addiction emphasize identifying all tobacco users in a physician's practice and ascertaining each patient's intent with respect to quitting smoking (Fig. 46-2).⁹⁰ Identification of tobacco use is facilitated by the implementation of an office-based system so that patients are queried about tobacco use

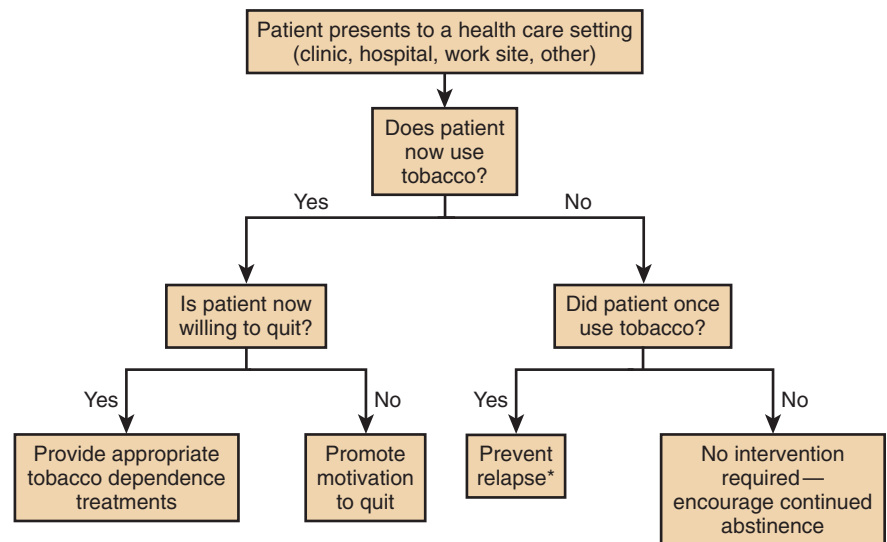

Figure 46-2 An algorithm for treating tobacco use. One of the main interventions is the first step, namely asking about and recording tobacco use at each office visit.

*Relapse prevention interventions are not necessary in the case of the adult who has not used tobacco for many years.

Table 46-6 Brief Strategies to Help the Patient Willing to Quit Tobacco Use—The “5 A’s”

Strategies for Implementation	Action
Ask—Systematically identify all tobacco users at every visit.	Implement an office-wide system that ensures that, for every patient at every clinic visit, tobacco-use status is queried and documented.
Advise—Strongly urge all tobacco users to quit.	In a clear, strong, and personalized manner, urge every tobacco user to quit.
Assess—Determine willingness to make a quit attempt.	Ask every tobacco user if he or she is willing to make a quit attempt at this time (e.g., within the next 30 days).
Assist—Aid the patient in quitting.	Help the patient with a quit plan. Provide practical counseling (problem solving/skills training). Provide intra-treatment social support. Help patient obtain extra-treatment social support. Recommend the use of approved pharmacotherapy except in special circumstances.
Arrange—Schedule follow-up contact.	Schedule follow-up contact, either in person or via telephone.

Adapted from A clinical practice guideline for treating tobacco use and dependence: 2008 update. A U.S. Public Health Service report. *Am J Prev Med* 35:158–176, 2008.

at every visit. Tobacco use should be treated as a vital sign by using tobacco status stickers on patients’ charts, electronic medical records, or computer reminder systems. The practice of routinely recording a patient’s tobacco use status increases the OR for quitting by twofold.

Brief strategies to help a patient quit (the “5 A’s”) (Table 46-6), which can be implemented in as little as 3 minutes, increase cessation rates significantly. In a meta-analysis of 31 trials, brief physician advice increased quit rates by 70%.⁸⁹ Intensive behavioral treatment of tobacco dependence produces higher success rates than brief advice does and is cost-effective. However, these intensive programs are less widely available and may be less acceptable to patients than brief interventions. Nevertheless, clinicians with training in intensive smoking cessation therapy should be identified as a referral source for smokers who are interested.

Multiple smoking cessation smart phone applications are now available to patients, but unfortunately they rarely adhere to guidelines. Although text messaging has not been demonstrated to enhance cessation rates, it may lead to lower consumption.⁹¹ This field of research in preventive

medicine is expanding rapidly, particularly in diabetes and hypertension care, and recent federal policy changes are becoming more supportive of preventive counseling. As services expand, there is a concomitant increased attention to the health-related costs of smokers and an increasing trend of businesses not to hire smokers.⁹²

Public Health Service guidelines recommend that all smokers trying to quit should be offered pharmacotherapy (Table 46-7).⁹⁰ In brief, three types of medications have been approved by the U.S. Food and Drug Administration (FDA) for smoking cessation—nicotine, bupropion, which was originally marketed as an antidepressant drug, and varenicline (Table 46-8). Other drugs such as nortriptyline and clonidine have been shown in clinical trials to be effective in aiding smoking cessation but have not been approved by the FDA for this purpose.

SMOKING CESSATION COUNSELING

Counseling smokers about the dangerous effects of tobacco should be routine medical practice and has been shown to be an effective method of improving cessation rates. Based

Table 46-7 General Clinical Guidelines for Prescribing Pharmacotherapy for Smoking Cessation

- In general, all smokers trying to quit smoking should be offered pharmacotherapy.
- There are seven first-line smoking cessation medications—five types of nicotine replacement therapy, sustained-release bupropion, and varenicline. Varenicline or the combination of nicotine patch plus ad libitum short-acting nicotine products appears to be most effective. However, the choice of first-line therapy should be governed by patient preference, familiarity of the clinician with the medication, contraindications for specific patients, and prior experience of the patient with specific pharmacotherapies.
- Second-line therapies include clonidine and nortriptyline. These should be reserved for individuals with contraindications to/or failure of response to first-line medications.
- Bupropion and nicotine replacement therapies may delay but not prevent weight gain after smoking cessation. It is recommended that patients start or increase physical activity, but strict dieting is discouraged because this appears to increase the likelihood of relapse to smoking. Patients should be reassured that weight gain after quitting is self-limited and poses much less of a risk to health than smoking.
- Transdermal nicotine (patches), nicotine gum, and bupropion appear to be safe for patients with chronic cardiovascular disease. Other medications are likely to be much safer than smoking in the presence of medical disease but need further evaluation.
- In smokers with prolonged withdrawal symptoms or in those who cannot resist smoking without medication, long-term therapy with nicotine replacement medication, bupropion, or varenicline appears to be safe and effective therapy.
- Recent research suggests that combining bupropion with nicotine patches or combining nicotine patches with ad libitum use of nicotine gum or nicotine nasal spray increases abstinence rates compared to the rates produced by a single form of therapy.

Adapted from A clinical practice guideline for treating tobacco use and dependence: 2008 update. A U.S. Public Health Service report. *Am J Prev Med* 35:158–176, 2008.

on a review of 188 randomized trials, personal advice and encouragement to stop smoking provided by a physician during a routine office visit resulted in an estimated 2% of all smokers stopping and not relapsing over 1 year.⁹³ Although this percentage seems low, it is both cost-effective and important when considering the large population and the risk for disease. Specific patient populations may have better results—8% of pregnant smokers, 21% of healthy men at risk for cardiovascular disease, and 36% of survivors of myocardial infarction will stop smoking when receiving advice and encouragement. This high success rate reflects the patient's inherent motivation once challenged by a condition that has been caused or may be aggravated by cigarette smoking.

Group counseling is less cost-effective than brief advice but may be necessary for smokers who are having a hard time quitting with less intensive therapy. A review of 16 studies comparing group counseling found increased rates of cessation compared to self-help programs (16 studies; OR = 2.0) or no intervention (6 studies; OR = 2.2).⁸⁹ There is no evidence that group counseling is more effective than a similar intensity of individual counseling.

Telephone counseling is effective in promoting cessation. In a large randomized, controlled trial of 1973 intensively counseled callers versus 1309 controls, telephone counseling through the California Quitline nearly doubled abstinence rates.⁹⁴ The 12 months' self-reported cessation rates

for those who made one or more cessation attempts was 23.3% in the treatment group and 18.4% in the control group. A recent meta-analysis of quit line trials confirmed the benefit of this intervention and suggested that multiple calls provided more benefit than a single call.⁹⁵ Telephone hotlines for smoking cessation are available at no cost in many states across the United States. Thus the busiest physician can easily refer patients to a hotline for cessation if personal counseling time is not readily available.

In-hospital counseling is found to be effective for patients admitted with cardiovascular disease but is not well studied in other populations. Counseling may also be enhanced with concurrent pharmacotherapy. In a randomized, controlled trial of 274 patients, Molyneux and associates⁹⁶ found that nicotine replacement therapy given with brief counseling is more effective than counseling alone or usual care. Counseling alone was not more effective than usual care, and differences between all groups disappeared at 12 months. These findings underscore the value of cessation medications when given with even brief advice. Longer physician counseling time and more office visits translate into higher cessation rates, independent of pharmacotherapy. Inpatient counseling from nurses and respiratory therapists can significantly improve cessation rates and should be routine clinical practice to maximize the “teachable moment” available during a hospitalization.⁹⁷

PHARMACOTHERAPY OF SMOKING CESSATION

Nicotine Replacement Therapy

Currently three medications have been approved for smoking cessation: nicotine, bupropion, and varenicline. All types of smoking cessation medications, if used properly, double smoking cessation rates compared with placebo treatments.^{90,98}

Nicotine replacement medications include nicotine polacrilex gum, transdermal nicotine patches, nicotine nasal spray, the nicotine inhaler, and nicotine lozenges. All seem to have comparable efficacy, but, in a randomized study, compliance was greatest for the patch, lower for gum, and very low for the spray and the inhaler.⁹⁹ A smoker should be instructed to quit smoking entirely before beginning nicotine replacement therapies.

Nicotine gum should be used with instructions to chew slowly, to chew 8 to 10 pieces per day for 20 to 30 minutes each, and to continue for an adequate period for the smoker to learn a lifestyle without cigarettes, usually 3 months or longer. Side effects of nicotine gum are primarily local and can include jaw fatigue, sore mouth and throat, upset stomach, and hiccups.

Transdermal nicotine patches are marketed in several preparations—some deliver 21 mg over a 24-hour period, and one delivers 15 mg over a period of 16 hours. Most brands have lower-dose patches for tapering. Patches are applied in the morning and removed either the next morning or at bedtime, depending on the patch. Patches intended for 24-hour use can also be removed at bedtime if the patient is experiencing insomnia or disturbing dreams. Full-dose patches are recommended for most smokers for the first 1 to 3 months, followed by one to two tapering doses for 2 to 4 weeks each.

Table 46-8 Suggestions for the Clinical Use of Pharmacotherapies for Smoking Cessation

Pharmacotherapy	Precautions/ Contraindications	Adverse Effects	Dosage	Duration	Availability
FIRST-LINE					
Bupropion hydrochloride, sustained release	History of seizure History of eating disorders	Insomnia Dry mouth	150 mg every morning for 3 days then 150 mg twice daily (begin treatment 1–2 wk prequit)	7–12 wk maintenance up to 6 mo	Prescription only
Nicotine gum	Temporomandibular joint disorder	Mouth soreness Dyspepsia	If 1–24 cigarettes/day, 2 mg gum (≤ 24 pieces/day) If ≥ 25 cigarettes/day, 4 mg gum (≤ 24 pieces/day)	Up to 12 wk	OTC only
Nicotine inhaler		Local irritation of mouth and throat	6–16 cartridges/day	Up to 6 mo	Prescription only
Nicotine nasal spray	Chronic nasal disorders, including rhinitis, polyps, and sinusitis	Nasal irritation Throat burning	8–40 doses/day	3–6 mo	Prescription only
Nicotine patch	Skin diseases, such as atopic or eczematous dermatitis	Local skin reaction Insomnia	21 mg/24 hr 14 mg/24 hr 7 mg/24 hr 15 mg/16 hr	4 wk then 2 wk then 2 wk 8 wk	Prescription and OTC
Nicotine lozenge	None	Nausea, hiccups, heartburn	If time to first cigarette >30 min, 2 mg; if time to first cigarette <30 min, 4 mg, up to 20 per day	12 weeks	OTC only
Varenicline	Significant kidney disease Patients on dialysis	Nausea Abnormal or vivid strange dreams Depressed mood and other psychiatric symptoms Trouble sleeping	0.5 mg/day for 3 days, 0.5 mg twice /day for 4 days, then 1 mg twice/day (begin treatment 1 wk prequit)	3–6 mo	Prescription only
SECOND-LINE					
Clonidine	Rebound hypertension	Dry mouth Drowsiness Dizziness Sedation	Initial 0.10 mg twice daily, titrate to 0.15–0.75 mg/day	3–10 wk	Prescription only (oral formulation) Prescription only (patch)
Nortriptyline	Risk for arrhythmias	Sedation Dry mouth	Initial 25 mg/day, titrate to 75–100 mg/day	3–6 mo	Prescription only

OTC, over-the-counter.

Adapted from A clinical practice guideline for treating tobacco use and dependence: 2008 update. A U.S. Public Health Service report. *Am J Prev Med* 35:158–176, 2008.

Nicotine nasal spray, one spray into each nostril, delivers about 0.5 mg nicotine systemically and can be used every 30 to 60 minutes. Local irritation of the nose commonly produces burning, sneezing, and watery eyes during initial treatment, but tolerance develops to these effects in 1 to 2 days.

Nicotine inhalers actually deliver nicotine to the throat and upper airway, where it is absorbed similarly to the nicotine from gum. It is marketed as a cigarette-like plastic device and can be used ad libitum.

Nicotine lozenges are available over the counter in 2-mg and 4-mg strengths and are to be placed in the buccal cavity, where they are slowly absorbed over 30 minutes.¹⁰⁰ Smokers are instructed to choose their dose according to how long after awakening in the morning they smoked their first cigarette (a measure of the level of dependence). Those who smoke within 30 minutes are advised to use the 4-mg lozenge, whereas those who smoke their first cigarette at 30 or more minutes are advised to use the 2-mg lozenges. Use is recommended every 1 to 2 hours.

Nicotine medications seem to be safe in patients with cardiovascular disease and should be offered to cardiovascular patients.^{101–103} Although smoking cessation medications are recommended by the manufacturer for relatively short-term use (generally 3 to 6 months), the use of these medications for 6 months or longer is safe and may be helpful in smokers who fear relapse without medications. There is also evidence that treatment of smokers with nicotine patches before smoking cessation results in decreased cigarette consumption and subsequently higher quit rates.¹⁰⁴

Bupropion

Bupropion sustained release (Zyban) is a dopamine-norepinephrine reuptake inhibitor originally marketed and still widely used as an antidepressant. Bupropion was found to aid smoking cessation whether or not a smoker was depressed.¹⁰⁵ Hurt and colleagues demonstrated that, with a 300-mg sustained-release dose, 44% of patients quit at 7 weeks versus 19% of controls. This difference was sustained at 12 months (23% versus 12%). This study also indicated

that when smokers quit they gain less weight while taking bupropion compared to placebo. An additional randomized, placebo-controlled trial demonstrated that the combination of bupropion with nicotine patch was safe, and that bupropion alone or in combination was as effective or more effective than patch alone.¹⁰⁶ Bupropion used for 1 year for relapse prevention was demonstrated to be safe and effective and significantly better at promoting cessation (55%) than placebo (42%).¹⁰⁷ Given its antidepressant properties, bupropion is a logical choice for depressed smokers but, as mentioned previously, has clear efficacy in smokers without depression as well.

Bupropion is dosed at 150 mg sustained release per day for 3 days, then 150 mg twice daily. Bupropion should be initiated 1 to 2 weeks prior to the quit date, then continued at 300 mg/day for the next 6 to 12 weeks. Bupropion in excessive doses can cause seizures and should not be used in an individual with a history of seizures or with eating disorders (bulimia or anorexia).

Varenicline

Varenicline, available by prescription only, is a nicotinic receptor partial agonist that selectively binds to $\alpha 4\beta 2$ nicotinic cholinergic receptors in the brain.¹⁰⁸ This receptor mediates dopamine release and is thought to be the major receptor involved in nicotine addiction. A partial agonist means that the drug both activates the receptor and blocks the effects of other agonists on the receptor. Varenicline activates the $\alpha 4\beta 2$ nicotinic cholinergic receptor with a maximal effect about 50% that of nicotine and, at the same time, blocks effects of nicotine from tobacco use on the receptor. As a consequence of the receptor stimulation, nicotine withdrawal symptoms are relieved, and, as a consequence of receptor blockade, the rewarding effects of cigarettes are diminished. The latter effect reduces the desire to smoke and, in the case of a lapse, may prevent continued smoking.

In clinical trials, varenicline treatment for 12 weeks has been shown to be more effective than bupropion sustained release 300 mg and placebo.¹⁰⁹ With varenicline, bupropion, and placebo, continuous abstinence rates from 9 to 52 weeks were 23%, 15%, and 10%, respectively. Varenicline has also been shown to be effective in preventing relapse over 6 months.¹¹⁰

A recent meta-analysis suggests that varenicline is also more effective than nicotine replacement therapy alone. The major side effects of varenicline are nausea, vomiting, and insomnia.⁹⁸ A variety of neuropsychiatric side effects, including depression, psychosis, and suicide, have been reported anecdotally but were not observed in clinical trials.¹¹¹ The causal relationship between varenicline and these neuropsychiatric events has not been established because smoking cessation itself can be associated with mood disturbances, including suicidality. In any case, smokers treated with varenicline should be advised about possible neuropsychiatric effects and monitored for such events during treatment. Varenicline has been shown to be effective in promoting smoking cessation in patients with cardiovascular and with pulmonary disease.^{112,113} Cardiovascular safety concerns with varenicline have been raised with one meta-analysis showing a small but significant

increased risk but another meta-analysis showed no significant increase.^{114,115}

Varenicline is initiated in a dose of 0.5 mg per day for 3 days, then 0.5 mg twice daily for 4 days, followed by a maintenance dose of 1 mg twice daily. Begin treatment 1 week prior to quit date. Lower doses may be used if nausea is a problem at higher doses. Because varenicline is eliminated by the kidneys, dose reductions are required in the presence of severe renal disease. The approved duration of treatment is 3 months, with another 3 months optional for prevention of relapse.

Combination Therapy

Combined medications for smoking cessation are more effective than individual therapies, particularly when combining long-acting medications such as nicotine patch or bupropion with short-acting nicotine replacement therapy used at times of intense urges or cravings to smoke.⁹⁸ Only bupropion and transdermal nicotine in combination have been approved by the FDA. However, a number of studies have looked at various combinations of medications, and there have been no significant safety issues.^{107,116-118} Studies comparing different therapies have found that combinations are two to three times more effective than single medications used alone. A stepwise process that incorporates combination therapies after patients have failed single therapies would be logical and would balance the increased costs of additional medications with increased benefit.

MOTIVATING SMOKERS TO QUIT

The well-known association between cigarette use and lethal diseases such as lung cancer, myocardial infarction, stroke, and COPD is insufficient to motivate many cigarette smokers to quit. This is due to the effects of the addiction to nicotine, which include denial and rationalization, a part of all drug addictions. As described previously, many smokers depend on nicotine to cope with stressors encountered in daily life. The perceived stress-reducing effect of nicotine is rapid and readily available. In contrast, quitting for many smokers results in a period of intense dysphoria and dysfunction, which can easily be avoided by smoking one or more cigarettes. A telephone-based survey conducted in 1999 found that only 29% of smokers felt that they were at greater risk for myocardial infarction, and only 40% felt they were at greater risk for development of cancer compared to nonsmokers.¹¹⁹ This clearly indicates denial of risk and may explain why many smokers become motivated to quit only when they develop a medical condition later in life. Becoming a nonsmoker requires a profound change of self-image and a discovery of personal coping skills that may have not been used previously.

The physician's role in the motivation process can be substantial. The message to the smoker must be consistent and inspirational. Patients clearly respond to physician advice, and hopelessness can be allayed by describing the many options available for cessation medication and counseling. Smoking cessation is the most important health initiative many patients will ever undertake and is highly cost-effective for the health care system. It is difficult to address

smoking in patients when three or four medical issues are being managed in addition to smoking cessation. For this reason, a separate return appointment focused solely on smoking cessation is recommended.

Motivating patients to quit needs to be more than steering them away from disease, but also steering them toward greater self-control, self-expression, independence, and positive role modeling. Exercise during trials of smoking cessation may reduce anxiety, tension, and stress but was not found to be an independent predictor of success in a randomized, controlled trial.¹²⁰ Walking on a regular basis is a reasonable initial step and in many cases improves self-esteem and investment in health.

BENEFITS OF QUITTING

The benefits of quitting smoking are substantial for smokers of any age. A person who quits smoking before age 50 has half the risk for dying in the next 15 years compared with a continuing smoker.¹²¹ Life expectancy was shortened by more than 10 years among a large cohort of current smokers compared to never smokers; quitting at an earlier age (e.g., 25 to 34) extended life expectancy by 10 years compared to quitting later (e.g., 45 to 54), when the added life expectancy was 6 years.³ These results confirm the known dangers of smoking and must be translated into a heightened effort to help younger smokers quit.

Smoking cessation reduces the risk for developing lung cancer, with the risk falling to half that of a continuing smoker by 10 years and one-sixth that of a smoker after 15 years' cessation. Quitting smoking in middle age substantially reduces lung cancer risk, with a 50% reduction in risk if a lifelong smoker quits at age 55 compared with age 75.¹²² The risk for acute myocardial infarction falls rapidly after quitting smoking and approaches nonsmoking levels within 1 year of abstinence. Cigarette smoking produces a progressive loss of airway function over time that is characterized by an accelerated loss of *forced expiratory volume in 1 second* (FEV₁) with increasing age. Loss of FEV₁ due to cigarette smoking cannot be regained by cessation, but the rate of decline slows after smoking cessation and returns to that of nonsmokers (see Fig. 43-5).¹²³ Women who stop smoking during the first 3 to 4 months of pregnancy reduce the risk for having a low-birth-weight infant to that of a woman who has never smoked.

After quitting, smokers gain an average of 5 to 7 pounds, which is perceived by some smokers as undesirable and as a reason not to quit.¹²⁴ Smokers tend to be thinner because nicotine increases energy expenditure and suppresses a compensatory increase in food consumption.⁸² After they quit smoking, ex-smokers tend to reach the weight expected had they never smoked. On balance, the benefits of quitting far outweigh the risks associated with weight gain, and patients should be counseled accordingly.

RESOURCES FOR PHYSICIANS

Most hospitals have smoking cessation services available that will enable referral of smokers if deemed necessary. Most states have toll-free quit lines that can be accessed

through a national network at 1-800-QUIT-NOW (1-800-784-8669) and that provide smoking cessation information and counseling and have been shown to be effective.⁹⁴ Internet-based programs such as QuitNet (www.quitnet.com) can provide online chat rooms and can give smokers with access to a computer a sense of community with other smokers in a similar position. If patients do not have their own computer, the public library is a smoke-free environment where they can access computers. The American Lung Association has significant information and an online program called "Freedom From Smoking" to which patients can be referred (<http://www.ffsonline.org/>). The Centers for Disease Control and Prevention has information that can be downloaded for adults, youth, and Spanish-speaking patients (www.cdc.gov/tobacco/). Patients suspected of having underlying depression, anxiety, or other substance abuse disorders may benefit from psychiatric referral to evaluate these conditions known to reduce the likelihood of smoking cessation.

FEDERAL REGULATION OF TOBACCO

In 2009 the U.S. Congress, through the Family Smoking Prevention and Tobacco Control Act, gave the FDA the authority to regulate the manufacture, distribution, and marketing of tobacco products to protect public health.¹²⁵ The Act (1) restricts cigarette and smokeless tobacco sales, advertising, and marketing to youth; (2) prohibits "reduced harm" claims such as "light" or "mild"; (3) requires bigger and more prominent warning labels; and (4) gives the FDA authority to regulate product standards, including banning characterizing flavors (except menthol), and allows the FDA to reduce potentially toxic constituents, including nicotine (although nicotine levels cannot be reduced to zero). FDA regulation of the addictiveness of tobacco has the potential to substantially reduce the prevalence of cigarette smoking and resultant disability and death in the future.¹²⁶

ELECTRONIC CIGARETTES

Electronic cigarettes (also known as e-cigarettes or electronic nicotine delivery devices) heat a nicotine solution to generate an aerosol (called a *vapor*) that is inhaled, without the combustion of tobacco and its toxic constituents. The devices consist of a cartridge containing a liquid (propylene glycol, sometimes with vegetable glycerin, nicotine, and flavorings), a heating element, a battery, and a microchip (Table 46-9). E-cigarettes are marketed with claims of health benefit compared with smoking cigarettes; they are marketed for use in reducing and quitting smoking, for use when a person is forbidden to smoke cigarettes, and for use in avoiding generating smelly and irritating secondhand smoke. The prevalence of the use of e-cigarettes has exploded since they were first marketed in 2006, with an 11.4% prevalence of ever use and 4.1% prevalence of use in the past 30 days in the United States in 2011.¹²⁷ In the European Union in 2012, 20.3% of current smokers, 4.7%

Table 46-9 E-Cigarette Designs, Descriptions, and Brand Names

E-cigarettes come in various sizes and designs. All contain a cartridge, a heating element, and a battery and provide an aerosol containing nicotine.

Product	Description	Some Brands
Disposable e-cigarette 	Cigarette-shaped device consisting of a battery and a cartridge containing an atomizer to heat a solution (with or without nicotine). Not rechargeable or refillable and is intended to be discarded after product stops producing vapor.	NJoy, Blu, Green Smoke
Rechargeable e-cigarette 	Cigarette-shaped device consisting of a battery that connects to an atomizer used to heat a solution typically containing nicotine. Often contains an element that regulates puff duration and/or how many puffs may be taken consecutively.	V2 Cigs, Halo G6, Mark Ten
Pen-style, medium-sized rechargeable e-cigarette 	Larger than a cigarette, often with a higher capacity battery, may contain a prefilled cartridge or a refillable cartridge (often called a clearomizer). These devices often come with a manual switch allowing the smoker to regulate length and frequency of puffs.	eGo, Kanger EVOD, Halo Triton
Tank-style, large-sized rechargeable e-cigarette 	Much larger than a cigarette with a higher-capacity battery and typically contains a large, refillable cartridge. Often contains manual switches and a battery casing for customizing battery capacity. Can be easily modified.	Kanger Aerotank, Innokin iClear, Aspire Nautilus

From Grana R, Benowitz N, Glantz SA: Background paper on e-cigarettes (electronic nicotine delivery systems): prepared for the 7th meeting of the WHO Study Group on Tobacco Product Regulation. San Francisco, 2013, UCSF.

of ex-smokers, and 1.2% of never smokers reported having used an e-cigarette.^{127a} As of 2013, there are more than 400 brands on the U.S. market, and they vary in the size of the device, the size of the cartridge, and the strength of the battery. Some look like cigarettes and are disposable; others look like pens or cigars and have refillable tanks. E-cigarette liquids are sold over the Internet or in “vape” shops, in which the user can select the liquid, including the vehicle, nicotine concentration, and flavor.

There is currently considerable debate in the public health community about the safety and benefit of e-cigarettes. All agree that e-cigarettes could be a health benefit if people would use e-cigarettes and stop smoking cigarettes entirely. There are many anecdotal reports of people quitting smoking using e-cigarettes, and one controlled clinical trial showing noninferiority of e-cigarettes compared to nicotine patches for cessation with minimal counseling via quit lines.¹²⁸ However, the quit rates in this trial were low, and population survey data do not show that people who have used e-cigarettes are more likely to quit than those who have not.¹²⁹ Many e-cigarette users report smoking fewer cigarettes per day while using e-cigarettes, but the health benefits of such reduction are not clear, and there is concern that the availability of e-cigarettes when one cannot smoke conventional cigarettes may impede quitting, resulting in more smokers and more population harm.

There are also concerns about the potential toxicity of e-cigarettes. The products that were marketed initially were contaminated with tobacco-specific nitrosamines and alkaloids other than nicotine, which were extracted along with nicotine from tobacco. Some more recently marketed products do not have such contamination. Propylene glycol in aerosol form can be a pulmonary irritant and reduces

dynamic airway resistance.¹³⁰ E-cigarette use could be detrimental to people with asthma and COPD. Nicotine itself has some potentially deleterious effects on cardiovascular hemodynamics (increased heart rate and blood pressure) and may impair endothelial function and promote insulin resistance; however, its effects are certainly much less than those of the combustion products in cigarette smoke. In addition, some e-cigarettes deliver nanoparticles containing tin, nickel, and/or chromium, the toxicity of which is unknown.

The most important potential population harm may be the renormalization of cigarette smoking behavior, resulting in more youth initiation and fewer adults quitting smoking. Currently e-cigarette advertising is unregulated and includes the use of young models and celebrities to convey images of the product as glamorous and modern. Recent data indicate a substantial increase in e-cigarette use among youth, including a number of youth who have used e-cigarettes without ever having smoked conventional cigarettes.¹³¹ Whether such users become addicted to nicotine and become cigarette smokers later is unknown at this time.

At present e-cigarettes are not regulated in the United States, although the FDA has signaled its intention to do so.¹³² FDA regulation would be particularly useful in ensuring the safety of these products, in limiting marketing and access to youth, and in restricting use in situations where smoking is banned so as to both minimize environmental pollution with e-cigarette vapor and to mitigate the renormalization of smoking behavior. Some clinicians will likely recommend e-cigarette use to patients who have been unable to quit smoking using traditional counseling and medications, although the use of e-cigarettes in such a role has not been proven.

Key Points

- For most smokers, quitting smoking is the single most important intervention to improve long-term health and is highly cost-effective for the health care system.
- In addition to causing cancer and COPD, smoking increases the risk for other pulmonary diseases, including respiratory infection (including pneumococcal pneumonia and tuberculosis), desquamative interstitial pneumonitis, and idiopathic pulmonary fibrosis, and increases the incidence of cardiopulmonary complications after surgery and in critically ill patients.
- Compulsive tobacco use is sustained by the addictive effects of nicotine, which include pleasure, modulation of mood and arousal, and avoidance of withdrawal symptoms.
- Optimal smoking cessation interventions in a physician's office should include systematically asking about tobacco use at every visit, advising smokers to quit and assessing their willingness to do so, providing or referring for counseling, provision of pharmacotherapy, and follow-up to encourage continued abstinence or to manage relapses.
- Quitting smoking even in middle age substantially reduces the risk for lung cancer and cardiovascular disease.
- Electronic cigarettes that deliver a nicotine aerosol without tobacco combustion products are being mar-

keted with claims to reduce smoking, to aid quitting, and to use where conventional smoking is banned. The potential benefit of e-cigarettes at present is unknown. The greatest potential harm of e-cigarettes would be in the renormalization of cigarette smoking behavior, resulting in more youth initiation and fewer adults quitting smoking.

INTRODUCTION

Cystic fibrosis (CF) is a multisystem genetic disease that affects children and young adults. CF is the most common monogenetic disease in Caucasian populations. The disease is caused by mutations in the *CF transmembrane conductance regulator* (CFTR) protein, an anion channel expressed on the epithelial surface. CF is typified by the presence of chronic upper and lower respiratory tract infection leading to bronchiectasis and end-stage lung disease. Manifestations in the pancreas, gastrointestinal tract, skin, and male reproductive tract are also prominent.

Understanding the biology and treatment strategies in CF is important for several reasons. First, it is the most common cause of chronic respiratory failure in children and young adults. Second, CF is the most common reason for pancreatic exocrine dysfunction in children and young adults. Third, it is a major cause of bronchiectasis and pansinusitis, among other sinopulmonary conditions in this age group, and therefore figures prominently in the differential diagnosis of various syndromes. Finally, advances in CF research have provided a roadmap for the understanding of pathophysiology and treatment for other severe airway diseases including chronic obstructive pulmonary disease, asthma, and non-CF bronchiectasis.

Through an increased understanding of CF pathobiology, the partnership of academic and pharmaceutical research enterprises with a multinational team of care centers and the Cystic Fibrosis Foundation, CF care represents a model for the treatment of chronic, life-threatening disease. It also provides a seminal example of the potential for translational medicine to deliver scientific advances that have transformed a universally fatal condition by the advent of comprehensive care centers and targeted therapeutics. Future advances will capitalize on personalized therapies directed at the underlying cause of the disease.

This chapter highlights the current understanding of CF pathobiology, with particular emphasis on the role of CFTR in disease pathogenesis. Insights into diagnosis, prognosis, and natural history are explored. CF therapeutics, including a special emphasis on the development of new therapies that target the basic defect, are also described in detail.

HISTORICAL PERSPECTIVE

Descriptions of abnormally high sweat salinity in children associated with premature death date back to 1650, but the first comprehensive description of CF as a distinct clinical entity was published in 1938 by Anderson who named the disease “*cystic fibrosis of the exocrine pancreas*.”¹ In 1945, Farber described the condition as a generalized *mucoviscidosis* resulting from obstruction of exocrine glands, a theme that has engendered recent interest as further research has described innate abnormalities of CF mucus.² Also in the 1940s, clinical descriptions first linked mucoviscidosis to severe and recurrent lung infections. With the advent of effective antibiotics, antimicrobial therapy began to be used for treatment of severe pulmonary infections for the first time.

The onset of an extreme heat wave in the northeastern United States in the summer of 1948 led di Sant’Agnese to describe high salt concentrations in the sweat of infants with CF and introduce the concept linking abnormal ion transport with the clinical features of the disease.³ Hence the end organ dysfunction in the sweat gland caused by functional decrements in CFTR were among the first characteristics recognized with the disorder. In this seminal work, di Sant’Agnese demonstrated elevated levels of sodium and chloride in sweat in greater than 98% of subjects with CF, a finding that remains a cornerstone

underlying the diagnosis today and explains an old Irish folk saying that “if your baby tastes of salt, he is not long for this world.”

Before the discovery of the *CFTR* gene and description of the *CFTR* protein in 1989,⁴⁻⁶ early observations based on di Sant’ Agnese’s work led to postulation of a derangement of a chloride anion channel as central to disease pathogenesis. To measure this phenomenon, Gibson and Cooke developed the pilocarpine method of sweat chloride testing, which remains a key diagnostic test for CF.^{6a} Additional observations by Quinton demonstrated that the sweat gland in CF patients is impervious to chloride.^{7,8} At the same time, a number of contributions regarding abnormalities of ion transport within the nasal epithelium by Knowles and colleagues^{9,10} and subsequent membrane patch-clamp analysis of epithelial cells from the airways of patients with CF by Welsh and Liedtke¹¹ provided conclusive evidence of a defect in chloride permeability of plasma membranes in the lung, in addition to an associated abnormality in measures of sodium transport.^{9,10} Soon thereafter Frizzell¹² identified the role of *CFTR* as an ion channel tightly regulated by phosphorylation. Restriction fragment-length polymorphism mapping by Collins, Riordan, and Tsui^{5,13,14} located the *CFTR* gene, among the first human genes to be identified, to the long arm of chromosome 7. This finding helped set the stage for isolation and cloning of the *CFTR* gene and the most common mutation, F508del *CFTR*, ultimately leading to an improved understanding of CF pathogenesis and new molecular therapeutics directed toward the basic defect.¹⁵

EPIDEMIOLOGY

CF is the most common genetic disease in Caucasians, found in 1 in 2500 to 3500 live births in the United States with lesser frequencies among African Americans (1:17,000). There is a varied incidence in particular ethnic groups, ranging from 1:569 in an isolated Ohio Amish population to 1:90,000 in Asian populations.¹⁶

CFTR mutations are most prevalent in persons from or descended from central and Northern European populations. Non-European-descendent white populations demonstrate intermediate rates of *CFTR* mutations, and Native Americans, Asian populations, and black Africans demonstrate the lowest rates. Proposed reasons for the selectivity of *CFTR* mutations in these populations include a heterozygote advantage in epidemic illnesses such as cholera, tuberculosis, or plague; the former is of particular interest because the absence of *CFTR*-dependent chloride transport could confer an advantage on cyclic 3',5'-adenosine monophosphate (cAMP) activation by cholera toxin. Conversely, selectively lower rates of *CFTR* mutations in populations living in tropical or semitropical environs could be due to propensity for dehydration and salt wasting. In white populations, 1 in 25 Caucasians are carriers for gene mutations,¹⁷ resulting in a carrier rate of 2% to 5%. CF carriers do not exhibit manifestations of CF illness, although carrier status has been proposed to increase the propensity and/or severity of respiratory disorders such as asthma and rhinosinusitis.^{18,19}

GENETIC BASIS

CF is an autosomal recessive disease caused by single gene mutations of the *CFTR* gene on the long arm of chromosome 7.^{5,13,14} This gene encodes a full-length protein in the *adenosine triphosphate (ATP) binding cassette (ABC)* transporter family, sharing primary and secondary structural elements with other membrane pump proteins from this family. The approximately 250 kB *CFTR* gene encodes for 27 exons for a full-length protein consisting of two membrane-spanning domains, two *nucleotide binding domains* (NBDs), and a single *regulatory domain* (R domain). A schematic proposed structure of the *CFTR* protein is shown in Figure 47-1.

There are many causative *CFTR* mutations, with more than 1900 recently described.¹⁶ Despite this, relatively few mutations account for the majority of *CFTR* alleles and are particularly common in the northern European descent population (Table 47-1). For example, the most frequent 159 mutations account for 96% of CF-causing alleles. The most prevalent mutation is F508del (c.1521_1523delCTT), which causes a 3-base pair deletion that results in omission of phenylalanine at position 508. This mutation accounts for about 75% of all *CFTR* alleles, though the distribution of this mutation is heterogeneous among particular ethnic populations and as high as 86% in Northern European Caucasians.¹⁶

F508del *CFTR* causes protein misfolding, resulting in endoplasmic reticulum-associated degradation. F508del is the prototypical class II mutation (mutations that result in premature degradation or incomplete maturation). Other mutations fall into several classes on the basis of molecular mechanism (Fig. 47-2). This includes incomplete synthesis due to *premature termination codons* (PTCs, class I); disordered regulation and gating, causing diminished ATP binding and hydrolysis (class III), which includes the G551D mutation; defective chloride conductance (class IV); and a reduced number of *CFTR* transcripts due to a promoter or splicing abnormality (class V). Mutations in class I, II, and III tend to cause severe *CFTR* functional abnormalities, whereas class IV and V mutants often exhibit preserved function (i.e., mild/variable mutations). Understanding the molecular abnormality in each mutational class is important for addressing the defect via pharmacologic agents such as *CFTR* modulators, discussed later in this chapter.

Despite robust knowledge of the various mutations in *CFTR*, still only 90% of CF patients have identified disease-causing mutations, although this is increasing with more frequent use of protein sequencing. In addition, the pathogenetic role of many mutations remains unknown but is being determined in a centralized fashion through the “CFTR2” project (www.CFTR2.org).²⁰ Some common variants such as M470V have been determined to be common polymorphisms rather than disease-causing alleles, although they may have a role in expression of the F508del defect.¹⁶ Others, such as the poly T sequence located within intron 10, can modify *CFTR* expression, thus acting as an important covariate to disease expression.²¹

The functional basis of various *CFTR* mutations allows correlation of genotype to phenotype, although *CFTR* genetics alone explain only some of the outcome of CF patients. For example, when two severe (class I, II, or III)

Figure 47-1 CFTR structure and domain assembly. Schematic representing the proposed structure of the cystic fibrosis transmembrane conductance regulator (CFTR) in its closed (*left*) and open (*right*) configurations. The two transmembrane spanning domains consist of six alpha helices each and together form the channel pore. Gating of the channel is controlled by the two intracytoplasmic nucleotide binding domains (NBD1 and NBD2) as they bind and hydrolyze ATP (hexagons), in addition to a regulatory domain (R), which contains numerous sites of phosphorylation. Normal activation of the protein requires phosphorylation of the regulatory domain. The NBDs bind and hydrolyze ATP, inducing channel gating by conferring opening of the pore through interfaces with the transmembrane domains via their extracellular loops (symbolized by dotted lines), which also function to stabilize the overall protein structure. The location of the F508del mutation (red dot) is on the surface of NBD1, compromising its stability and interrupting interactions with the transmembrane domains.

mutations are present, pancreatic insufficiency usually results (especially in those patients homozygous for F508del). The presence of two severe mutations also confers risk for severe phenotypic manifestations including meconium ileus and hepatobiliary disease. Alternatively, the presence of one or more mild/variable mutations may confer enough residual CFTR function to alter expression or severity. CF patients with mild mutations have intermediate sweat chloride, which correlates with the presence of pancreatic sufficiency.^{16,22} When two mild/variable mutations are present, atypical forms of CF arise, such as congenital absence of the vas deferens, idiopathic pancreatitis, or late-onset respiratory disease without other characteristic features of the CF syndrome.^{21,23-25}

Disease severity and expression can also be affected by non-CFTR genetic modifiers, which have received significant attention in the last decade. *Transforming growth factor* (TGF)- β has repeatedly been shown to modify disease severity, even among subjects homozygous for F508del CFTR.^{26,27} Other genetic modifier loci on chromosome regions 4q35, 8p23, 11q25, and 19q13 confer increased risk of meconium ileus,^{28,29} and various modifiers are associated with acquisition of *Pseudomonas aeruginosa* infection.^{30,31}

PATHOPHYSIOLOGY

CFTR AS AN ABC GENE

CFTR is categorized as a member of the ABC or traffic ATPase family of genes.^{15,32,33} These ancient genes code for

hundreds of polypeptides from both prokaryotes and eukaryotes, which transport nutrients, metabolites, toxins, and other small molecules across cellular membranes. All ABC proteins are characterized by two NBDs encoding canonical Walker A and B motifs (capable of binding and hydrolyzing ATP). ABC proteins also contain two *membrane-spanning domains* (MSDs) with multiple alpha helices that form highly selective passageways across lipid bilayers. Among ABC proteins, CFTR is atypical by virtue of a *regulatory domain* (R domain) with numerous sites for protein kinase A/cAMP-dependent protein kinase (cAMP/PKA) phosphorylation, as well as a *regulatory insertion* (RI) in *nucleotide binding domain 1* (NBD1) believed to participate in channel gating^{15,34,35} (see Fig. 47-1).

STRUCTURE/ACTIVITY AND CFTR GATING MECHANISM

The CFTR gene product is composed of approximately 1500 amino acids and functions as a transporter of Cl^- and HCO_3^- in numerous epithelial tissues. Although a high-resolution, three-dimensional structure of full-length CFTR is not yet available, site-directed mutagenesis indicates that gating is enabled by cAMP/PKA dependent phosphorylation of the R domain. The phosphorylation step has been shown to elicit a conformational change in the regulatory insertion, leading to NBD1/NBD2 heterodimerization and structural realignment in MSD1 and MSD2 that open the ion conductive pore.³⁶ Key interactions between the intracellular loops of the transmembrane domains and the nucleotide binding domains are integral to protein stability and interdomain

assembly, as well as to transmission of the forces required for channel opening (see Fig. 47-1).³⁷⁻³⁹ NBD dimerization is greatly augmented when two ATP binding sites (at the NBD1/2 interface) are occupied; closing of CFTR is attributable to ATP hydrolysis.^{40,41} It should be noted that ATP binding is not absolutely required for channel gating (so-called ATP-independent channels can also open, presumably on the basis of the tendency of NBDs to bind each other spontaneously).⁴¹ Transepithelial transport through CFTR is governed by the electrochemical driving force, and a CFTR bioelectric signature (by membrane patch clamp analysis or planar lipid bilayer reconstitution) describes an approximately 8 picosiemens channel with linear current/voltage relationship and characteristic opening bursts. CFTR therefore employs ATP binding to enable passive ion transport, rather than subserving the function typical of the ABC gene family (i.e., pumping of larger metabolites with a stoichiometric dependence on ATP hydrolysis).

BIOGENESIS AND PROCESSING OF NATIVE CFTR

Wild-type CFTR matures by a conventional pathway that includes cotranslational insertion in the *endoplasmic reticulum* (ER) membrane and post-translational modifications

such as N-linked glycosylation and ubiquitination (Fig. 47-3). Subdomain folding (e.g., within NBDs) and achievement of final tertiary structure requires complex domain binding interactions and represents a topic of intense interest due to the importance of misfolding as a mediator of clinical disease.^{37,38,42,43} As even wild-type CFTR processing is not completely efficient, a subset of CFTR molecules is targeted for proteosomal hydrolysis by *ER-associated degradation* (ERAD). For CFTR that advances from ER to Golgi, complex glycosylation takes place at two asparagine residues. CFTR reaching the Golgi is transported to the cell surface by vesicular traffic with subsequent recycling through sorting and recycling endosomes and reinsertion in the plasma membrane or routing to the lysosome. The cell surface apparatus that governs CFTR peripheral stability (i.e., plasma membrane) has been well characterized and includes ubiquitin conjugation to regulate internalization in response to environmental stress.⁴⁴

CELLULAR DEFECTS ATTRIBUTABLE TO F508DEL CFTR

The vast majority of F508del CFTR is retained in the ER, heavily ubiquitinated, and routed to the proteasome by ERAD.⁴⁵ As a consequence, F508del CFTR visualized by SDS PAGE is predominantly an ER localized, approximately 150KDa core glycosylated ("band B") glycoform, whereas a substantial portion of post ER, wild-type protein migrates more slowly due to complex glycosylation (\approx 180 KDa "band C"). The F508del trafficking defect is temperature sensitive, and growth of epithelium at lower temperatures (e.g., 27°C) leads to measurable levels of band C with partial restoration of cell surface function.

The maturational processing defect mediated by F508del involves at least two distinct abnormalities.^{37,38,46} Omission of F508 (which is located on an externally exposed peptide loop of the first nucleotide binding domain) leads to pronounced loss of NBD1 stability as judged by thermal and isothermal calorimetry, protein aggregation, and protein yield measurements following recombinant overexpression. In addition, F508 facilitates binding of a cytosolic loop from MSD2, and disruption of the NBD1/MSD2 interface (independent of NBD1 stability) leads to further impairment of F508del maturation.

F508del CFTR molecules that have been rescued to the cell surface by low temperature display intrinsic channel gating abnormalities, diminished plasma membrane stability, and pronounced thermal unfolding with loss of function following incubation at 37°C.^{47,48} In addition, F508del CFTR mRNA may be misfolded and poorly utilized (leading to lower levels of CFTR translation) due to omission of the F508 codon.^{49,50} The observation of multiple distinct CFTR defects attributable to F508del points to the challenge of identifying a single agent capable of restoring mutant CFTR to therapeutically relevant levels. Intramolecular suppressor mutations that specifically ameliorate F508del NBD1 instability or the defective NBD1/MSD1 interface have been identified.^{37,38} CFTR constructs encoding these suppressors provide a means to characterize F508del corrective strategies and will enable compound library screening tailored to specific CFTR folding defects in the future.

Figure 47-2 CFTR mutations and molecular consequences. Classes of defects in the *CFTR* gene product include the absence of synthesis (*class I*); defective protein maturation and premature degradation (*class II*); disordered regulation, such as diminished ATP binding and hydrolysis (*class III*); defective chloride conductance or channel gating (*class IV*); and a reduced number of CFTR transcripts due to a promoter or splicing abnormality (*class V*).

Figure 47-3 Scheme of CFTR biogenesis. Biogenesis of CFTR in normal epithelial cell (right side of cell) and F508del cystic fibrosis (CF)-affected epithelial cell (left side). In the normal epithelial cell, CFTR is synthesized in the rough endoplasmic reticulum, glycosylated and folded in the Golgi apparatus, and chaperoned to the cell surface. In the F508del-affected epithelial cells, the CFTR polypeptide is misfolded and tagged for premature degradation via endoplasmic reticulum-associated degradation (red arrow) before reaching the cell surface (*class II* mutation). (Adapted from Ameen N, Silvis M, Bradbury NA: Endocytic trafficking of CFTR in health and disease. *J Cystic Fibrosis* 6:1–14, Fig. 1, 2007.)

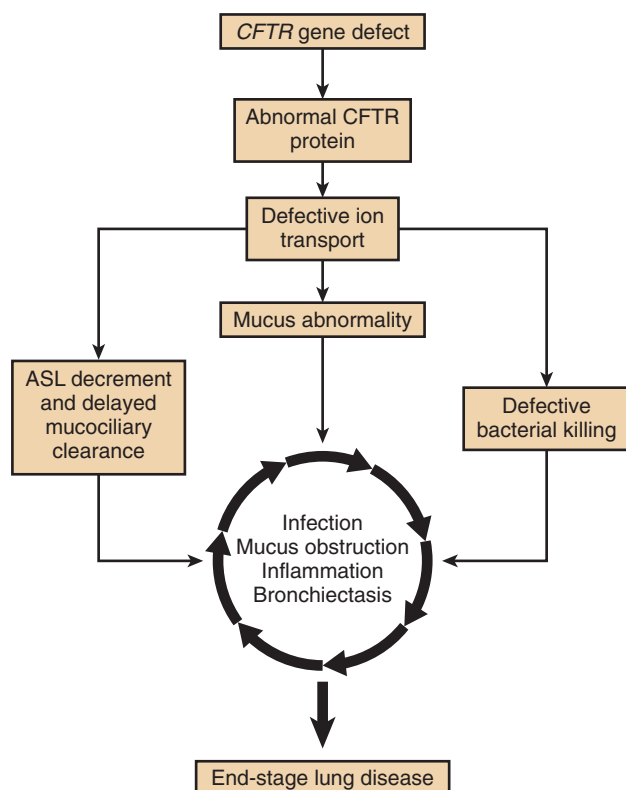

Figure 47-4 CF pathophysiology. CF lung disease results from consequences of genetic mutations in *CFTR*. Major operative pathways include reduced mucociliary clearance due to depleted airway surface liquid (ASL) hydration, abnormal mucus adhesion and viscosity, and defective bacterial killing that each contribute to the cycle of destruction.

OVERVIEW OF LUNG PATHOPHYSIOLOGY

An improved understanding of CF pathogenesis has led to better diagnostic strategies, an improved understanding of the onset and progression of lung disease, and therapeutic approaches to target the underlying disease. An overview is provided in [Figure 47-4](#) and described in further detail later. As with other monogenetic diseases, absent or dysfunctional *CFTR* results in diminished functional protein, which is necessary to transport chloride and bicarbonate across the airway epithelium. Several key manifestations include delayed mucociliary clearance because of depletion of *airway surface liquid* (ASL), abnormalities of the physical properties of CF mucus, and a predisposition to early infection because of abnormal mucosal defense; there may also be dysregulated inflammation. These processes initiate and perpetuate a cycle of destruction that ultimately results in irreversible lung injury, bronchiectasis, and respiratory failure.^{15,51}

In the lungs, CF manifests as infected mucus secretions that compromise the airway lumen and contribute to obstructive pulmonary disease and reduced FEV₁ ([Fig. 47-5](#)). Airway disease is thought to begin in the small airways, resulting in airflow obstruction detected by spirometry midflows (i.e., FEF_{25%-75%}). Submucosal gland hyperplasia and inspissated mucus secretions emanating from the glands are also prominent. Radiographic changes consistent with small airway obstruction (e.g., tree-in-bud

opacities) followed by bronchiectasis become apparent over time. Development of bronchiectasis leads to irreversible changes that encourage continued infection and accelerate disease pathogenesis.

CELLULAR FUNCTIONS OF THE *CFTR* GENE PRODUCT

The *CFTR* gene is hundreds of millions of years old and utilized by diverse species including fish, amphibian, fowl, and mammalian. Although best described as a chloride and bicarbonate transporter, the protein appears to regulate numerous processes in addition to anion secretion. *CFTR* is situated within membrane complexes by virtue of a PDZ-type binding motif and configured in close proximity to a number of integral membrane proteins including other ion channels. In experimental systems, *CFTR* exerts a regulatory influence on the *epithelial sodium channel* (ENaC).⁵² Proteomic and transcriptome analyses demonstrate hundreds of cellular gene products that directly bind or are regulated by the gene product.⁵³

REGULATION OF AIRWAY SURFACE LIQUID HOMEOSTASIS

In a conventional model of CF respiratory pathogenesis, absence of apical *CFTR* leads to failure of chloride and bicarbonate secretion.^{15,52} Because release of water into the periciliary region is driven in large measure by a *CFTR*-dependent osmotic gradient, *CFTR* deficiency leads to failure of ASL hydration ([Fig. 47-6](#)). In addition, a considerable body of evidence suggests that ENaC present on the airway surface may be down-regulated by wild-type *CFTR*, and that loss of the *CF* gene confers elevated ENaC-dependent sodium and water uptake, further exacerbating ASL desiccation. According to this prevailing model, depleted ASL leads to inadequate ciliary extension and impairment of mucociliary clearance.^{54,55}

Recent findings indicate significant new levels of complexity with regard to the mechanisms that govern ASL depth and mucociliary clearance. For example, although the periciliary fluid layer has traditionally been viewed as primarily aqueous in composition, recent data indicate that a fluid layer containing tethered mucins is characterized by intrinsic viscosity that is sensitive to the osmolar forces of the overlying mucus, which are expected to strongly influence mucociliary clearance when the periciliary layer collapses due to mucus dehydration.⁵⁶ Moreover, ENaC hyperactivity across the CF airway surface—thought to be a hallmark of CF pathophysiology in the past—has recently been questioned on the basis of (1) absence of sodium hyperabsorption from airway mucosa in newborn CF pigs (together with evidence of normal ASL depth) and (2) studies of primary human airway epithelium indicating that elevated sodium reabsorption in CF can be explained by an increased gradient for sodium uptake (rather than a direct biochemical influence on ENaC, per se).^{15,57-59}

Findings such as these pose a challenge to interpretation of experimental therapies intended to augment ASL depth by blocking respiratory ENaC or activating non-*CFTR* chloride secretory pathways. Such interventions represent an important approach for improving mucociliary clearance,

Figure 47-5 CF pathologic and radiologic correlation. **A**, Gross pathologic specimen of explanted CF lung from a patient with end-stage CF lung disease. This specimen demonstrates heavy lungs characterized by bronchiectasis and numerous mucopurulent plugs. **B**, Large airway pathology of CF. A large mucus plug filled with inflammatory infiltrate is clearly seen, in addition to remodeling of the medium-sized airway (hematoxylin-eosin stain). **C**, Representative photomicrographs from a CF patient with end-stage lung disease is depicted. Note the thickening of the lamina propria (higher Reid index), the prominent arborized mucus plug extruding from the submucosal gland onto the airway lumen, and the hypertrophic surface epithelium (periodic acid-Schiff stain). **D**, Sagittal high-resolution CT image from a 16-year-old male with CF demonstrating mild to moderate multilobar bronchiectasis (cyan arrows) and tree-in-bud opacities representing small airways mucus plugs (red arrow). (A–C, Images courtesy Dr. David Kelly, University of Alabama, Birmingham.)

and such strategies could improve mucus clearance regardless of their relationship to the fundamental CF defect. The significance of ASL expansion is underscored by therapeutic improvement among patients treated with hypertonic saline aerosols and dry powder mannitol to improve mucociliary clearance in CF lung disease by providing airway hydration.

REGULATION OF SWEAT CHLORIDE BY CFTR

The concentration of chloride in human sweat is determined by the balance of secretion and reabsorption of sodium and chloride in the sweat gland and duct. Chloride is secreted by two parallel pathways. One involves CFTR; the other utilizes a CFTR-independent, calcium-activated chloride channel. Because CFTR is not the only pathway by which chloride exits the apical membrane, chloride is secreted into sweat even in the absence of functional CFTR. Normally, sodium is reabsorbed in the duct of the sweat gland because of ENaC in the apical membrane of the duct cells. Chloride follows sodium into the cell, through the

CFTR chloride channel. In CF, with absent or defective CFTR, chloride reabsorption is significantly reduced and the chloride content of sweat is abnormally high.

CYSTIC FIBROSIS EXOCRINE GLANDULAR EPITHELIUM

Submucosal glandular ducts filled with inspissated mucus are observed early in the course of CF pulmonary involvement. CFTR is heavily expressed within epithelial cells of submucosal glands, where it functions to activate fluid and electrolyte secretion and promote release of mucus onto the airway surface.⁶⁰ The relative contributions of submucosal glands to overall CF respiratory pathophysiology are not known. Although absence of a lung phenotype in CF murine models has been attributed to non-CFTR Cl^- secretory pathways that are highly active in mouse lungs,⁶¹ the paucity of murine airway glands has also been implicated (see Chapter 1 for differences in mouse and human lungs). The relative lack of murine airway glands is a likely explanation for the lack of a murine lung phenotype, particularly

because other CF null animals with extensive submucosal gland formation (i.e., pig, ferret) exhibit a pulmonary phenotype similar to humans. The recent development of confocal imaging modalities that allow direct visualization of glandular activity in full-thickness airways and the ability to analyze biophysical properties of mucus extruded from CF pig, ferret, or rat submucosal glands⁶² will contribute new and important knowledge in this area.

MUCUS BIOGENESIS, ADHESION, AND TRANSPORT

Hyperviscous respiratory secretions obstruct small- and medium-sized airways in CF, leading to profound failure of mucociliary clearance that can be verified macroscopically by radioligand imaging.⁶³ A primary biochemical defect in mucus composition has been extensively sought but not well established as a fundamental cause of the disease. Studies of CF pulmonary secretion are complicated

by difficulty retrieving standardized mucus samples, the diversity of respiratory pathogens, pronounced lung inflammation, and other variables. Specific mucins expressed in CF respiratory secretions include the gel-forming mucins MUC5B and MUC5AC, in addition to a complex array of extracellular proteins.⁶⁴ DNA strands released from dying bacteria, epithelial cells, and inflammatory cells represent an important contributor to excess mucus viscosity and provide rationale for use of recombinant DNase as an aerosolized mucolytic.

In extrapulmonary CF organs characterized by hyperviscous secretion (e.g., pancreas, liver), profound ductular obstruction is observed in the absence of polymicrobial infection, allowing more direct studies of the relationship between CFTR and mucus formation. An emerging notion implicates defective bicarbonate transport as a mediator of hyperviscosity and mucosal adhesion in CF secretions. In this model, exocrine mucus (highly negative in charge) is produced by acinar and other epithelial cells in compacted

Figure 47-6 CF airway surface and mucus transport defect. Schematic of the mucociliary transport defect in CF. In the healthy state (**A**), adequate airway surface homeostasis ensures effective transport of mucus extruding from airway surface goblet cells and the submucosal glands. The airway surface liquid (ASL) is maintained by fluid secretion via the CFTR and fluid absorption via the epithelial sodium channel, ENaC (inset box on right) (CFTR, surface receptor in blue; ENaC, surface receptor in red). In CF (**B**), the ASL is depleted through the absence of CFTR-mediated fluid secretion accompanied by tonic fluid absorption via the ENaC. CFTR-dependent liquid dessication decreases the depth of the ASL including the periciliary layer causing abnormal clearance of mucus from the epithelial cell surface in the airways.

Continued

Figure 47-6, cont'd

form due to bound calcium, which shields the negative repulsive force between sulfates and other anionic groups on constituent mucins.² Bicarbonate secretion via CFTR chelates the calcium and permits mucinous expansion and a viscoelastic state compatible with physiologic clearance. Failure of bicarbonate release is hypothesized to result in a defective mucin expansion, leading to hyperviscous secretion with abnormally adherent properties (i.e., mucus that is tightly bound to the respiratory surface and difficult to mobilize). Evidence of excessive mucus adhesion that can be reversed by bicarbonate has been observed in the intestine of CF mice.^{65,66}

HOST DEFENSE AND INFECTION

CF lungs are characterized by intense neutrophilic inflammation with polymorphonuclear cells densely infiltrating airway secretions. Whether robust lung inflammation is mediated directly by CFTR (as opposed to a consequence of polymicrobial infection) is a topic of considerable debate.^{67,68} Neutrophil chemoattractants such as interleukin-8, tumor necrosis factor (TNF)- α , and a collagen fragment, proline-glycine-proline, are present at high levels in airway secretions, and abnormalities of CFTR-dependent macrophage function have also been implicated. Although

anti-inflammatory therapies can improve lung function and slow the rate of CF respiratory decline, immune blockade also can predispose individuals to worsening lung infection, and the proper clinical balance has been difficult to achieve.⁶⁹

Bacteria typically colonize the CF respiratory tract during infancy or early childhood. Longitudinal analysis of *P. aeruginosa* indicates sentinel infection due to a single genotype of the organism that often persists throughout the life of an individual patient.⁷⁰ The explanation for early colonization is not well understood. Previous studies have suggested increased binding of CF pathogens to CFTR $-/-$ airway epithelial cells or that antimicrobial peptides present in pulmonary secretions are inactivated by high salt concentrations bathing the respiratory surface.^{71,72} A recent study implicated acidic pH within CF ASL (attributable to absent CFTR bicarbonate release) as a likely cause of the increased susceptibility to bacteria.⁷³ Findings such as these are most relevant to initial colonization events because airway pH may not be affected later in life.

Virulent respiratory pathogens such as *P. aeruginosa* evolve in a stereotypic fashion during the lifespan of individuals with CF and are characterized by rapid phenotype change and hypermutability.⁷⁴ After several years of pulmonary infection, *P. aeruginosa* typically develops a

mucoïd phenotype in which considerable metabolic reserves are expended to synthesize and release the polyanionic protein, alginate. Appearance of mucoïd *P. aeruginosa* in CF is a negative prognostic indicator. Selective advantage of alginate release has been attributed to the immunomodulating role of this exoproduct.^{75,76} Recent studies have demonstrated the complexity of the CF microbiome, which can be altered during exacerbation by the presence of a dominant pathogen.⁷⁷

Porcine and ferret models of CF pulmonary disease, as well as identification of very young CF patients by newborn screening, provide an important means to clarify relationships that exist among initial bacterial colonization, chronic infection, and inflammation in CF lungs. Longitudinal monitoring of CF respiratory infection in humans and transgenic animals will also facilitate a more sophisticated understanding of the complex CF microbiome and could provide new therapeutic opportunities in the future.

CFTR AND PULMONARY REMODELING

Measurements in the CF porcine model indicate a change in tracheal diameter and density of submucosal glands before the advent of hyperviscous mucus obstruction. Similar findings have been reported in human CF lungs and in *Cftr* $-/-$ rats (despite the absence of mucus plugging in the rodent model).⁷⁸ In tissues such as porcine and human pancreas, fibrotic damage and fatty replacement can be profound, with extensive parenchymal scarring.⁷⁹ Myofibroblast proliferation appears to mediate this effect, and TGF- β signal transduction (which engenders myofibroblast transformation) is markedly increased throughout the CF lung.⁸⁰ TGF- β is also a well-established genetic modifier of F508del homozygous CF lung disease,^{26,81} and these findings suggest that changes in TGF- β -dependent profibrotic pathways govern lung tissue remodeling (in addition to inflammatory responsiveness elicited by the cytokine).

DIAGNOSIS

OVERVIEW

The diagnosis of CF is predicated on clinical suspicion for the disease, as indicated by clinical manifestations or family history, or alternatively through newborn screening programs. Early detection through newborn screening is leading to earlier recognition of illness before the clinical characteristics become apparent. The first organized CF newborn screening programs were developed in the 1980s and implemented in Colorado in 1987 and in the 1980s in Australia and Europe⁸² after retrospective trials demonstrated improved mortality and clinical outcomes.⁸³ The number of programs in the United States and abroad increased in the past decade, and now all U.S. states have implemented newborn screening programs after a CDC/Cystic Fibrosis Foundation Consensus Statement in 2004 recommended this practice.⁸⁴ The report invoked emerging prospective data that screening and early interventions in CF newborns diagnosed by newborn screening improved nutritional, gastrointestinal, respiratory, and cognitive functioning.⁸⁵⁻⁸⁸

Several different screening algorithms are used and vary by state program, but serum detection of *immunoreactive trypsinogen* (IRT) is typically the primary screening method. IRT is quantified from blood spots taken in the perinatal period. IRT is a highly sensitive serum marker of obstructive pancreatic injury, although it is not specific for CF and thus additional testing is required to confirm the diagnosis. Elevated IRT in the perinatal period is typically followed by repeat IRT testing and/or a DNA panel for common CFTR mutations. If positive, refer to a diagnostic clinic for assessment of CFTR through mutation analysis and functional assays, such as sweat chloride, to confirm the diagnosis; this is frequently accomplished before the onset of clinical manifestations.

Diagnostic Algorithms

The diagnosis of CF is based on a positive newborn screening test or suspicious clinical characteristics in patients in infancy through adulthood (Table 47-2). In 2008, the Cystic Fibrosis Foundation published comprehensive diagnostic guidelines for infants and adults with suspected CF⁸⁹ (Fig. 47-7A and B); a similar approach was adopted in the European CF Society's 2006 guidelines. The guidelines primarily differed only in the timing of CFTR mutation analysis and sweat chloride normative values.⁹⁰ In addition, as compared with the European diagnostic guideline, the U.S. guideline deemphasizes measurement of *nasal potential difference* (NPD), a bioelectric measure of CFTR activity, mainly due to lack of standardization, although NPD is recommended as an alternative diagnostic modality. There is good concordance when comparing these methodologies for diagnostic accuracy.⁹¹

Table 47-2 Diagnostic Criteria for CF by Clinical Phenotypic and CFTR Functional Abnormalities

The diagnosis of CF is confirmed by the presence of:

Appropriate phenotypic clinical features (any of):

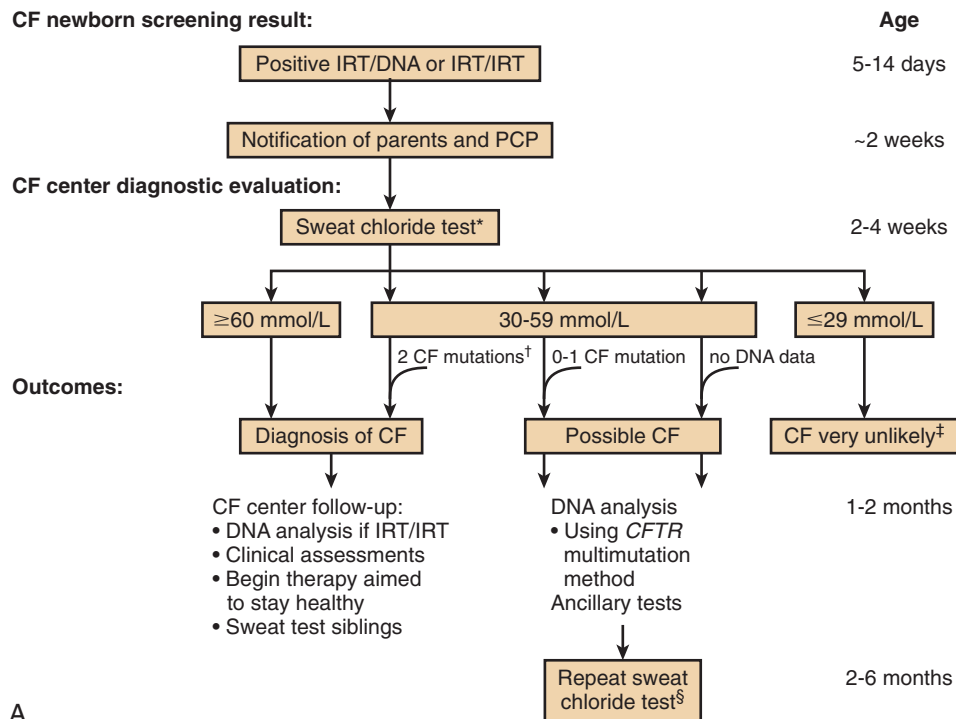

- Chronic sinopulmonary disease
- Chronic cough and sputum production
- Persistent infection with characteristic pathogens (*Staphylococcus aureus*, *Pseudomonas aeruginosa*, other gram-negative organisms)
- Airflow obstruction
- Chronic chest radiographic abnormalities
- Sinus disease; nasal polyposis
- Gastrointestinal and nutritional abnormalities
- Exocrine pancreatic insufficiency
- Recurrent pancreatitis
- Fat-soluble vitamin deficiency
- Meconium ileus; DIOS
- Obstructive azoospermia in males

Plus,

Laboratory evidence of CFTR dysfunction (one or more of following):

- Elevated sweat chloride
- Disease-causing mutation in CFTR gene in both alleles
- Characteristic bioelectric abnormalities (potential difference) in nasal epithelium
- Abnormal ex vivo intestinal short-circuit current measurement

CF, cystic fibrosis; CFTR, cystic fibrosis transmembrane conductance regulator; DIOS, distal intestinal obstruction syndrome.

A

* If the baby is at least 2 kg and more than 36 weeks' gestation at birth, perform bilateral sweat sampling/analysis with either Gibson-Cooke or Macroduct method; repeat as soon as possible if sweat quantity is less than 75 mg or 15 μ L, respectively.

† CF mutation refers to a *CFTR* mutant allele known to cause CF disease.

‡ The disease is very unlikely; however, if there are two CF mutations in trans, CF may be diagnosed.

§ After a repeat sweat test, further evaluation depends on the results as implied above.

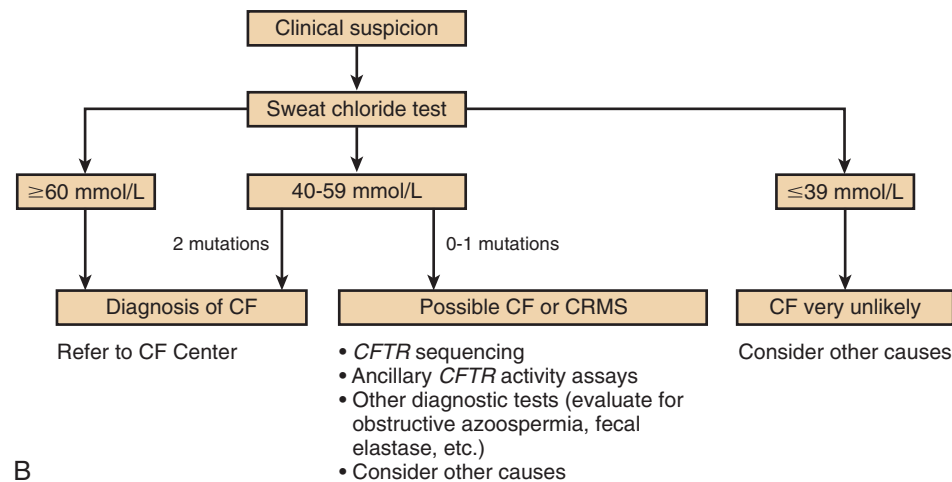

Figure 47-7 Diagnostic algorithm for CF. **A**, Schematic depiction of the diagnostic algorithm for the diagnosis of CF in infants emphasizing newborn screening programs. **B**, Schematic depiction of a diagnostic algorithm for children and adults emphasizing sweat chloride as the cornerstone of the diagnosis. Note the differences in the lower limit of normal of sweat chloride for infants versus children and adults. Genetic testing for intermediate probability cases should trigger *CFTR* sequencing since analysis for only limited number of mutations can result in false negative evaluations in this disease category. CRMS, *CFTR*-related metabolic syndrome; IRT, immunoreactive trypsinogen; IRT/DNA, means confirmation with a DNA assay (see text); IRT/IRT, confirmation with a second IRT test; PCP, primary care physician. (**B**, Adapted from Farrell PM, Rosenstein BJ, White TB, et al: Guidelines for diagnosis of cystic fibrosis in newborns through older adults: Cystic Fibrosis Foundation consensus report. *J Pediatr* 153(2):S4–S14, 2008.)

In the North American (CFF) algorithm (see Fig. 47-7A), newborns are screened for CF using IRT, a byproduct of prenatal pancreatic inflammation. In most states this test is paired with a DNA probe panel for common *CFTR* mutations. IRT is not a highly specific measurement due to

elevated levels observed in prematurity, traumatic delivery, and other neonatal gastrointestinal disorders.⁹² Because of declining IRT levels in the first few months after birth in CF and non-CF infants,⁹³ this test is only useful for screening in the first few weeks after birth. Thereby, family history or

clinical suspicion based on symptoms is the main impetus for diagnostic evaluation after the neonatal period has passed (see Fig. 47-7B).

If the IRT is elevated or in situations where CF is suspected, the diagnosis should be confirmed by sweat chloride testing. Sweat chloride testing is available in many clinical laboratories and has been standardized to ensure accuracy. Because of its high sensitivity, sweat chloride testing has a central role in establishing the diagnosis in both the Cystic Fibrosis Foundation and European algorithms in the presence of a positive newborn screening or compatible clinical characteristics.

For infants screened at birth, a low sweat chloride value (<29 mmol/L) effectively rules out CF, whereas a high sweat chloride concentration (≥ 60 mmol/L) definitively establishes the diagnosis. In the case of clinical suspicion with an intermediate sweat chloride concentration (30 to 59 mmol/L), guidelines recommend performing *CFTR* sequencing or high-sensitivity DNA probe testing to establish the presence of *CFTR* mutations. If two *CFTR* mutations are found, the diagnosis of CF is established. If one or zero mutations are present, then repeat sweat chloride testing is recommended. It should be noted that standard genetic panels (i.e., panels that test fewer than 40 mutations) are not sufficient in patients with elevated sweat chloride and atypical manifestations because rare, partially functional mutations are common in these cases and may not be detected in limited panels. Some patients exhibit CF-like disease even in the absence of *CFTR* mutations, a finding probably caused by mutations in genes coding for other related proteins that can mimic mutations in *CFTR* (i.e., mutations in the ENaC channel).⁹⁴

If clinical suspicion remains elevated and sweat chloride is in the intermediate range, there are several alternatives to confirm *CFTR* functional deficits. NPD testing, available at select CF specialty centers, is viewed as an acceptable alternative in cases of inconclusive sweat chlorides values or inadequate genetic analysis. Testing of intestinal current measurements, another alternative, is only available at a few centers in the world and requires a biopsy of the rectal mucosa.^{95,96} Additionally, other measures of pancreatic function such as fecal elastase may help to support the diagnosis in this setting.

In analogous fashion, children and adults with clinical syndromes suspicious for CF are also first screened for *CFTR* dysfunction using sweat chloride testing (see Fig. 47-7B). If the sweat chloride is low (≤ 39 mmol/L) CF is ruled out and other causes of the clinical syndrome should be sought. The lower limit of normal for sweat chloride values is higher in adults due to a relative, normal increase in sweat chloride with aging. In the presence of an elevated sweat chloride (>60 mmol/L), the diagnosis of CF is established in the patient and referral to a CF specialty center is recommended. In the case of an intermediate sweat chloride value (40 to 59 mmol/L), further *CFTR* genetic testing (i.e., sequencing) or alternative diagnostic testing as described earlier are appropriate. Additionally, in adult males, the diagnosis may be strongly suggested by the presence of a positive urologic evaluation for obstructive azoospermia.

It is increasingly recognized that *CFTR*-related disorders represent a spectrum of disease, with pancreatic-insufficient CF as the most severe form (Fig. 47-8). It is notable that

functional assessments of *CFTR* reflect this diversity, although the relationship between genotype and *CFTR* functional decrements can vary. *CFTR* biomarkers are generally able to distinguish between mild and severe phenotypes by demonstrating a continuum of *CFTR* decrement that correlates to clinical phenotype and is not apparent by genotype alone.²²

CLINICAL MANIFESTATIONS

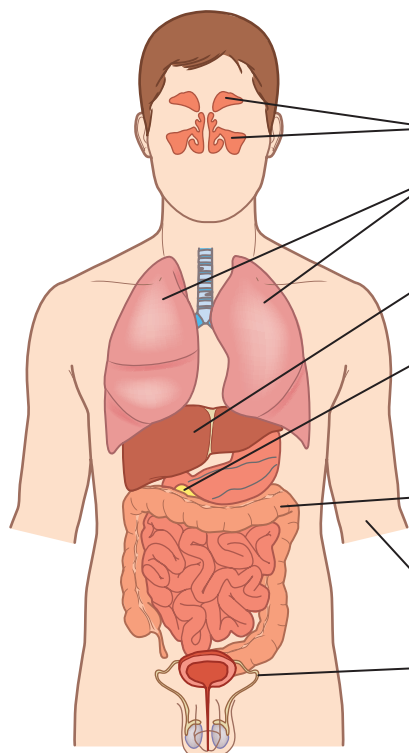

CF has historically presented with protean manifestations with symptoms that may mimic or resemble other disease processes. Usual presentations include early onset of respiratory tract symptoms, particularly persistent cough and recurrent or refractory chest radiographic changes. Gastrointestinal presentations are also prominent and include meconium ileus in approximately 15% of patients and failure to thrive with steatorrhea due to pancreatic insufficiency. A list of unusual presentations is compiled in Table 47-3, and presentations that are common during adolescence or early adulthood due to residual levels of *CFTR* activity are highlighted. Clinical severity can vary widely; less severe disease states can be initially misdiagnosed as other more common respiratory conditions.

With the widespread acceptance of newborn screening programs in the United States, it is now typical to diagnose CF before the onset of respiratory disease. Although this has tremendous clinical benefit, a high index of suspicion must be maintained to ensure diagnosis in the event of a screening failure or in individuals born before the initiation of screening programs. Consequently, a significant number of CF patients may present in adulthood because symptoms are unusual, subtle, or even absent early in life, resulting in a delayed presentation. Oftentimes these nonclassic presentations are due to partially active *CFTR* alleles or other ameliorating mutations.⁹⁷ Recognition of the variable manifestations of CF is required to detect CF, either in childhood or later in life.

LOWER RESPIRATORY TRACT DISEASE

Progressive obstructive lung disease leading to bronchiectasis and respiratory failure causes the vast majority of mortality in individuals with CF. Even seemingly healthy infants with CF have significant subclinical lung disease; inflammation is often disproportionate to the degree of infection.⁹⁸ The most common manifestation of lung disease is cough in association with bronchitis. Early in life, symptoms are often intermittent and exacerbated by episodes of acute respiratory tract infection that tend to exhibit a protracted course. With time, cough becomes a daily event. It is often worse at night and on arising in the morning. With progression or during exacerbations of lung disease, cough can become productive of tenacious, mucopurulent sputum secondary to chronic bacterial infection and resultant neutrophilic inflammation.

Hyperinflation of the lungs is common and often observed early in the progression of lung disease.⁹⁹ Asthmatic or bronchiolitic-type wheezing is common during the first 2 years of life but may be encountered at any age. Wheezing is noted in up to one third of infants and may be present

Organ System	CF-Pancreatic Insufficient	CF-Pancreatic Sufficient	CFTR-Related Disorder*
Typical genotype	Two severe mutations	At least one mild/variable mutation	Two mild mutations or heterozygous
Sinus	Chronic sinusitis	Chronic sinusitis	Chronic sinusitis
Airways	Severe chronic bacterial infection	Chronic bacterial infection, later onset, variable	Chronic bacterial infection, mild, later onset, variable
Liver	Severe hepatobiliary disease (5%-10%)	Usually absent	Absent
Pancreas	Exocrine insufficiency	Adequate exocrine function until late in life, pancreatitis (pancreatitis in minority)	Adequate exocrine function, pancreatitis (can be presenting symptom)
Bowel	Risk of meconium ileus, DIOS	Nonspecific bowel complaints, low risk of DIOS	Nonspecific bowel complaints
Sweat chloride	90-110 mmol/L	60-90 mmol/L	40-60 mmol/L
Vas deferens	Obstructive azoospermia	Obstructive azoospermia	Normal, CUAVD, or CBAVD
Endocrine Pancreas	High risk of CF-related diabetes mellitus	Low risk of CF-related diabetes mellitus	Minimal risk of CF-related diabetes mellitus

Figure 47-8 Spectrum of CF disorders. This figure compares the findings in severe CF with the milder forms of the disease. Although manifestations are variable, severity in each organ system is generally consistent with degree of CFTR dysfunction conferred by genotype. CBAVD, congenital bilateral absence of the vas deferens; CUAVD, congenital unilateral absence of the vas deferens; DIOS, distal intestinal obstruction syndrome. *Refers to CFTR-related metabolic syndrome or CFTR-related disorders which are being defined currently.

Table 47-3 Atypical Presentations of Cystic Fibrosis*

Respiratory	Bronchiolitis/asthma <i>Pseudomonas aeruginosa</i> or <i>Staphylococcus aureus</i> colonization of the respiratory tract Staphylococcal pneumonia Nasal polyposis Nontuberculous mycobacterial infection
Gastrointestinal	Meconium plug syndrome Rectal prolapse Recurrent abdominal pain and/or right lower quadrant mass Hypoproteinemic edema Prolonged neonatal jaundice Biliary cirrhosis with portal hypertension Vitamin deficiency states (A, D, E, K) Acrodermatitis enteropathica–like eruption with fatty acid and zinc deficiency Recurrent pancreatitis
Genitourinary	Male infertility Female infertility
Other	Hypochloremic, hyponatremic alkalosis Mother of a child with cystic fibrosis

*Presentations noted in **boldface** are those that may present in adolescents or adults with cystic fibrosis.

with or without evidence of atopy.¹⁰⁰ Early in life, CF may often mimic the clinical manifestations of asthma and/or coexist with asthma syndrome, leading to delayed recognition.

Lung sounds are often unremarkable early in the disease process; the first detectable abnormalities may be a diminished intensity of breath sounds or subtle prolongation of the expiratory phase. Once CF lung disease becomes clinically apparent, adventitious lung sounds are usually first noted in the upper lobes. CF patients may have only mild bronchitic symptoms for long periods of time as lung homeostasis is maintained but typically manifest exacerbations of symptoms of increased cough intensity and sputum production. These exacerbations often present as tachypnea, shortness of breath, malaise, anorexia, and weight loss. Viral respiratory tract infection is a frequent trigger, as are other infectious agents, cigarette smoke,¹⁰¹ pollutants,¹⁰² allergens, and respiratory irritants that have been implicated in disturbing lower airway homeostasis. Initiation of broad-spectrum antibiotic therapy and aggressive maneuvers to facilitate clearance of mucus are usually required to improve symptoms and restore lung function. These pulmonary exacerbations are now recognized as a major driver of disease progression, and greater attempts to recognize and treat them before irreversible injury have

Figure 47-9 Alterations in sputum microbiology with age. This figure depicts increasing chronic infection with *Pseudomonas aeruginosa* and methicillin-resistant *Staphylococcus aureus* (MRSA) with advancing age based on data from CF centers in the National CF Patient Registry. This is contrasted with the higher prevalence of *Haemophilus influenzae* and methicillin-sensitive *S. aureus* in childhood and adolescence. MDR-PA, multidrug-resistant *P. aeruginosa*. (Data from the Cystic Fibrosis Foundation Patient Registry; Bethesda, MD; 2012).

become a priority.¹⁰³ As lung disease progresses, exacerbations characteristically become more frequent and severe, often requiring extended courses of *intravenous* (IV) antibiotics and hospitalization. End-stage lung disease associated with impairment of daily activities heralds a sequence of terminal events in the absence of lung transplantation, including hypoxemia, pulmonary hypertension, cor pulmonale, respiratory failure, and death.

MICROBIOLOGY

Patients with CF demonstrate colonization of the airways early in life with bacteria characteristic for the disease. Chronic infection of the lower airways, once established, is difficult to eradicate. *Staphylococcus aureus* and *Haemophilus influenzae* are usually the first organisms detected and often present with a benign clinical picture (Fig. 47-9).¹⁰⁴ Historically, acquisition of *P. aeruginosa* or *Burkholderia cepacia* was regarded as a particularly ominous clinical finding because these infections are associated with accelerated decline in lung function and increased mortality.¹⁰⁵ With the increased prevalence of microbiologic screening and more aggressive antimicrobial treatment regimens, a more broad and diversified group of respiratory pathogens has emerged.¹⁰⁶ These pathogens include *methicillin-resistant S. aureus* (MRSA), multidrug-resistant gram-negative rods, atypical mycobacteria, and fungal organisms.¹⁰⁷ Often the clinical significance and factors contributing to the presence of these organisms in sputum culture are complex and multifactorial and thus require careful clinical consideration to determine the appropriate timing and intensity for treatment because some organisms may represent benign colonization.

The prevalence of *P. aeruginosa* increases with age, infecting greater than two thirds of patients by the third decade of life. The frequency of detection earlier in life has increased in the era of newborn screening and may be as high as 20% in children younger than 2; detection in infants at the time of diagnosis is not uncommon. Acquisition of *P. aeruginosa* increases longitudinally (see Fig. 47-9) and has been associ-

ated with genotype severity—individuals homozygous for F508del demonstrate a higher prevalence of chronic infection.¹⁰⁸

Considerable concern has emerged surrounding the nosocomial acquisition of new infections and transmission of multidrug-resistant organisms.¹⁰⁹ As the concept of eradication of initial infection has become standard practice, identification and earlier treatment of initial infection with *P. aeruginosa* using frequent respiratory sputum sampling to detect these inciting events is recommended in those not previously colonized.¹¹⁰⁻¹¹² Sputum bacteriology correlates reasonably well with specimens obtained directly from the lower respiratory tract, although microbial sequencing is lending new insights into the validity of this conclusion. Oropharyngeal swab cultures that yield *S. aureus* or *P. aeruginosa* are modestly predictive of results from bronchoscopic specimens, but negative pharyngeal cultures do not rule out the presence of these organisms in lower airways.¹¹³ Nevertheless, recent studies supporting sputum or oropharyngeal swab culture surveillance and subsequent treatment with intent to eradicate infection have demonstrated similar efficacy to more invasive detection regimens.¹¹⁴ Other more sensitive means to detect *P. aeruginosa*, such as PCR, may further improve sensitivity of noninvasive techniques. Quantitative bacteriology may be particularly useful for determining the relative contributions of isolated organisms.

As lung disease progresses, *P. aeruginosa* often becomes the predominant organism recovered from sputum and may be present in multiple strains with different antibiotic sensitivity patterns. The emergence of a mucoid phenotype due to elaboration of large amounts of alginate is associated with worsened clinical outcome.¹¹⁵ Mucoid organisms are found as microcolonies of pseudomonads embedded and growing in biofilms of alginate.¹¹⁶ Biofilms inhibit phagocytosis and enhance bacterial adherence while limiting exposure to antibiotics and reactive intermediates produced by leukocytes.¹¹⁷⁻¹²⁰ Although the presence of a mucoid phenotype is clearly associated with colonization, new mucoid *Pseudomonas* infection or conversion to mucoid phenotype

may also be amenable to aggressive eradication strategies.^{121,122} Isolation of *P. aeruginosa* from the lower respiratory tract of a child or young adult with chronic lung symptoms is highly suggestive of CF but has been reported in patients with primary ciliary dyskinesia or other severe obstructive lung diseases.¹²³

Although *P. aeruginosa* has remained the dominant pathogen in adult CF lung disease, MRSA has emerged as a significant contributor to disease progression and mortality. In contrast, methicillin-susceptible strains are associated with improved outcomes.¹²⁴ As MRSA has continued to emerge as a significant public health issue, its prevalence and severity in CF lung disease has become more evident.¹²⁵ Two studies using the U.S. CF registry have demonstrated an association between MRSA and worsened lung function, whereas another has shown MRSA infection to be an independent risk factor for mortality.^{126,127} Considerable interest has emerged in the epidemiology and biologic significance of the *staphylococcal chromosomal cassette* (SCC) containing the methicillin-resistance gene (*mecA*) and the *Panton-Valentine leukocidin* (PVL) expressing strains, both of which have an effect on their virulence and impact on disease severity.¹⁰⁷ Small-colony staphylococcus variants may also represent a distinct entity highly resistant to traditional therapy.¹²⁸

Many different gram-negative pathogens in addition to *P. aeruginosa* have demonstrated significant clinical impact on respiratory health, lending support to the consideration that CF lung infection represents a more complex microbiome than previously realized.¹²⁹ Of these, *B. cepacia* has remained the most ominous due to its inherent multidrug antibiotic resistance and association with rapid decline in respiratory health.¹³⁰ Infection can spread from patient to patient, leading to stringent infection control measures within CF care settings.^{131,132} Infection has been linked to the rapid demise of a small percentage of patients with what is referred to as “*cepacia* syndrome.”¹³³ Molecular analyses have shown that *B. cepacia* complex is composed of at least nine phenotypically indistinguishable but genetically distinct species known as genomovars.^{111,134,135} Genomovars II (*Burkholderia multivorans*) and III (*B. cenocepacia*) have been associated with the *cepacia* syndrome, and genomovar III includes the highly transmissible strain that may be linked to expression of the cable pilus.¹³⁵⁻¹³⁷ Other gram-negative rods present in sputum include mucoid *Escherichia coli*, *Stenotrophomonas maltophilia*, *Achromobacter xylosoxidans*, *Klebsiella*, and *Proteus*. Of these, *S. maltophilia* and *A. xylosoxidans* appear to have the strongest association with poor respiratory outcomes, but their clinical significance warrants further evaluation. Other gram-negative organisms such as *Pandoraea* and *Ralstonia* spp. have been isolated from CF sputum samples, but further clinical investigations are necessary to determine significant clinical associations. Obligate anaerobes have been identified from CF lung tissue; they are typically undetected by traditional clinical microbiologic samples but may be found in large abscess cavities on rare occasions.^{138,139}

Infection with nontuberculous mycobacteria is increasing in the CF population presumably due to concomitant antibacterial therapy resulting in a favorable ecologic niche, host susceptibility, improved detection, and environmental prevalence.¹⁴⁰⁻¹⁴⁵ Up to 20% of adult patients in some clinics

are colonized by nontuberculous mycobacteria. Although infection is often transient, the clinical impact of infection with these organisms appears to be increasing. *Mycobacterium avium* complex infection is of variable clinical significance, yet rapidly growing mycobacteria such as *Mycobacterium abscessus* can exhibit a more virulent course, prompting aggressive and long treatment regimens.¹⁴³ In contrast, *Mycobacterium tuberculosis* infection has only been seen in sporadic cases. Studies to standardize treatment for these emerging pathogens have been proposed.

Nearly 40% of individuals with CF will grow *Aspergillus fumigatus* in the sputum during their lifetime; patients who have severe lung disease appear to have an even higher incidence of sputum positivity.¹⁴⁶ The pathogenic potential of *Aspergillus* in an otherwise immunocompetent host is not well established. However, *Aspergillus* is clearly associated with allergic bronchopulmonary aspergillosis (ABPA). ABPA is present in approximately 2% of CF patients and adds a considerable burden of care.^{147,148} See ABPA in Chapters 38 and 48.

IMAGING

The earliest radiographic change in CF lung disease is usually hyperinflation of the lungs, reflecting obstruction of small airways. Central airway thickening and linear opacities, often producing a “tram-track” appearance, representing bronchiectasis, are eventually seen (eFig. 47-1) and often progress with age (eFig. 47-2). Frequently these findings are most easily appreciated in the right upper lobe (eFig. 47-3), and this lobe is often involved before other regions of lung are affected. The appearance of bronchiectasis at chest CT is characteristic (eFigs. 47-1B-E and 47-2B-E; see Chapter 48). Although chest radiography is appealing due to accessibility and relatively low doses of radiation exposure, its sensitivity for detecting acute or subtle chronic changes during a period of acute exacerbation remains limited.¹⁴⁹ Despite its limitations, chest radiographs remain the standard first-line imaging in surveillance and during acute exacerbations, episodes of hemoptysis (eFig. 47-4), or to identify complications such as pneumothorax¹⁵⁰ (eFig. 47-5); its use is recommended biannually in stable CF patients.¹⁵¹

High-resolution cross-sectional imaging using computed tomography (CT) is clearly superior for detecting mild disease and quantifying the extent and pattern of bronchiectasis (eFigs. 47-1B-E and 47-2B-E).^{152,153} Mosaic perfusion, manifesting as areas of inhomogeneous lung opacity and resulting from air trapping producing disordered pulmonary parenchymal perfusion resulting in maldistribution of pulmonary blood flow, is common at chest CT in patients with CF (eFig. 47-6). Small nodules resulting from bronchial and bronchiolar impaction are commonly seen at chest CT (eFig. 47-7). CT studies have demonstrated significant early changes in young children, before obvious clinical disease, supporting the notion that CF lung disease begins early in life and its detection is limited by the sensitivity of routine clinical procedures including spirometry.¹⁵² Regardless of the imaging modality used, the degree of hyperinflation generally increases over time. As endobronchial infection and reactive inflammation emerge, peribronchial cuffing becomes increasingly evident. Evidence of bronchiectasis,

such as enlarged ring shadows or airway dilation and cysts, is common even early in life (see eFig. 47-1); upwards of 50% of patients demonstrate bronchiectasis by 3 to 5 years of age.¹⁵³

During acute pulmonary exacerbations, a variety of radiographic findings may be noted such as peripheral round densities and mucoid impaction seen radiographically as branching opacities. These may resolve during treatment, replaced by the emergence of bronchiectasis or cystic changes. Additional findings including subpleural blebs often become evident during the second decade of life and are most prominent along the mediastinal border.¹⁵⁴

The indications for CT scanning in place of routine chest radiography are not established. One clear indication may be the evaluation of a patient with focal disease who may be considered for lobectomy, or patients that suffer acute deteriorations to help detect complications or evidence of new pathogens. *Magnetic resonance* (MR) imaging, which avoids radiation associated with CT scans, can also define lung morphology, particularly as techniques have improved, but the relative sensitivity and specificity of MR techniques have not yet been established.¹⁵⁵ MR-based ventilation scans are also possible using hyperpolarized gas; although they sensitively demonstrate airway obstruction, the method is generally restricted to research use due to poor availability and stability of the noble gases required.

LUNG FUNCTION

Lung function is believed to be normal at birth in infants with CF, though recent studies have demonstrated the cycle of inflammation and infection is present within weeks to months, and reduced cartilage size may impact early airway obstruction.¹⁵⁶ Infants with CF can exhibit increased airway resistance, gas trapping, and diminished flow rates.¹⁵⁷⁻¹⁵⁹ Many centers use infant pulmonary function testing to detect early evidence of airway obstruction and guide institution of therapeutic strategies before permanent lung injury. Lung clearance index, a test performed by measuring the time for clearance of an inert gas through multiple breath washout technique, is also emerging as a research tool to detect early evidence of ventilation abnormality and is not confounded by patient effort.¹⁶⁰⁻¹⁶² Reliable and consistent spirometry can be obtained routinely at 5 to 6 years of age when children are able to cooperate.^{163,164}

The earliest evidence of airway obstruction is typically limited to the small airways and thus is often first detectable by reduced forced midexpiratory flow rates, reduced flows at low lung volumes, and gas trapping (i.e., elevated *residual volume to total lung capacity* ratio [RV/TLC]). Although infrequently used in clinical applications, abnormalities such as increased alveolar-arterial oxygen gradient, frequency dependence of dynamic compliance, reduced response of flows to a helium-oxygen mixture, elevated slope of phase III of the single-breath nitrogen washout, and an elevated physiologic dead space are often present.¹⁶⁵ Spirometry is the most clinically useful test to follow the course of respiratory disease progression and is typically measured at each clinic visit. Equally important is assessment of the flow volume loop, which may demonstrate obstruction via concavity toward the volume axis before either the FEV₁ or FEF_{25%-75%} is affected.

Over time patients with active lung disease can experience a progressive deterioration of lung function; the annualized rate of decline in FEV₁ is approximately 2% to 3% of the predicted FEV₁ annually.¹⁶⁶ Despite recent advances, this progressive loss of lung function often accelerates in young adulthood.¹⁶⁷ As lung disease progresses, peripheral airway obstruction yields to more generalized obstruction and progressive air trapping late in the disease as airways cease to contribute to gas exchange, mimicking a restrictive pattern on spirometric measurements of lung function.¹⁶⁸

As the chronic cycle of inflammation and infection contributes to lung disease, many patients with CF begin to show mild decrements of arterial PO₂. Oxygenation declines slowly throughout life and this decline is often not clinically significant until late in the disease course. Patients who are able to sustain adequate oxygenation usually function well despite the presence of obstructive impairment. When arterial PO₂ values are sustained below 55 mm Hg, patients are at high risk for symptomatic pulmonary hypertension.^{169,170} Clinically significant hypoxemia most commonly presents during sleep, particularly during REM-associated hypoventilation, and is a significant factor leading to pulmonary hypertension.¹⁷¹ Desaturation at rest or with exertion as measured during a 6-minute walk are strong predictors of mortality.¹⁷² Elevation of arterial PCO₂ and FEV₁ less than 30% define end-stage disease. Patients with FEV₁ less than 30% of predicted, arterial PCO₂ greater than 50 mm Hg, or arterial PO₂ less than 55 mm have a predicted 2-year mortality of 50% and should be considered for lung transplantation.¹⁷³ Other prediction tools can also facilitate appropriate patient selection for referral and outperform reliance on any single criterion.¹⁷⁴

Bronchial hyperresponsiveness is a consistent finding in asthma, but its presence and clinical significance in CF remain controversial.^{175,176} Bronchial hyperresponsiveness in CF has been demonstrated during exercise testing, bronchoprovocation testing, or response to bronchodilators, with two thirds of CF patients demonstrating decreased forced expiratory flows after a bronchoconstrictive challenge. In contrast to cross-sectional studies, repeated tests every 1 to 3 months for a year have demonstrated bronchodilator responsiveness at least once in 95% of subjects.¹⁷⁷ Despite its frequency, the pathogenesis of bronchial hyperresponsiveness in CF is unclear. Hyperresponsiveness is unrelated to the severity of pulmonary disease or indices of atopy but seems to be more prevalent during winter months. Hyperresponsiveness diminishes with exacerbations of lung disease but returns as lung function improves after 2 weeks of intensive antibiotic therapy. Patients with CF may also have a lack of response to bronchodilators that may be related to loss of tone in bronchiectatic airways.

Exercise tolerance in CF is related to the severity of airway obstruction.¹⁷⁸ Nearly 50% of patients with moderate to severe airway obstruction may experience oxygen desaturation to below 90% during peak exercise.¹⁷⁹ Persons with CF have higher than expected ventilatory muscle endurance, and this endurance can be further improved with inspiratory muscle training. However, improved inspiratory muscle strength and endurance do not augment exercise performance.

Exercise therapy has many physiologic and biologic benefits but has not been convincingly demonstrated to improve

standard spirometry. Nevertheless, standardized aerobic and resistive exercise does improve cardiorespiratory fitness and *quality of life* (QOL) and has been associated with a reduced risk of hospitalization.¹⁸⁰ Maximum oxygen consumption during exercise may be a better predictor of survival than routine pulmonary function testing, but the test is time consuming and not available in all clinical settings.¹⁸¹ Several more clinically efficient measures of physical fitness show strong correlation with peak oxygen consumption and disease prognosis, further reinforcing that improvement of physical health through exercise may positively affect overall health in CF.¹⁸²

UPPER RESPIRATORY TRACT DISEASE

Chronic rhinosinusitis is present in virtually all patients with CF. CF sinus disease manifests as chronic, relapsing symptoms of increased upper airway secretions, moderate airflow obstruction, and widening of the nasal bridge.¹⁸³ This is seen at imaging (eFig. 47-8) as opacification of the paranasal sinuses in more than 90% of patients in the first year of life. Nasal polyps are seen in an additional 15% to 20% of patients.¹⁸⁴ Nasal polyps usually present toward the end of the first or during the second decade of life and may be the clinical finding that triggers diagnostic evaluation.¹⁸⁵ The presence of acute and chronic nasal obstruction can diminish olfactory function and may contribute to diminished dietary intake and subsequent nutritional decline.¹⁸⁶ Despite the presence of radiographic abnormalities, symptoms can be surprisingly well tolerated. Acute or chronic symptoms of sinusitis manifest in less than 10% of children and in approximately 24% of adults.^{187,188} Nevertheless, colonization of the upper airway may contribute to lower airway disease, necessitating attention to its presence and severity.

COMPLICATIONS OF RESPIRATORY TRACT DISEASE

Atelectasis is present in approximately 5% of CF patients during the first 5 years of life with diminishing frequency with advanced age.¹⁸⁹ Atelectasis may be lobar or subsegmental, with the right lung being the most commonly affected. Furthermore, it may develop concurrently with pulmonary exacerbations or in the absence of clinical symptoms. Occasionally, atelectasis may result from endobronchial aspergillosis presenting as mucoid impaction with volume loss.¹⁹⁰ However, in most instances, a discrete mucus plug is not evident on bronchoscopy.

Pneumothorax (see eFig. 47-5) is a well-recognized CF complication due to air trapping and subsequent rupture of subpleural blebs. Although the overall incidence is equal among sexes and fairly low (about 1% per year), this increases sharply with age and disease severity, with 20% of CF adults experiencing at least one pneumothorax during their lifetime.¹⁹¹ Typical presentations include acute onset of chest pain, dyspnea, respiratory distress, or hemoptysis.¹⁹² Tension pneumothorax, which is more common in CF than in other obstructive lung diseases, represents an emergent situation because the rapid accumulation of pleural air may become life-threatening. Similarly, simultaneous bilateral pneumothoraces have been described and consti-

tute an emergency. Small asymptomatic pneumothoraces may also be discovered in patients following routine surveillance chest radiography. Recurrent pneumothoraces are common.

Hemoptysis is a relatively common event in CF (see eFig. 47-4) and is believed to result from mucosal erosions and bronchial artery hypertrophy, which are a consequence of chronic inflammation.¹⁹³ The presence of hemoptysis correlates with disease severity and is more common in the setting of chronic MRSA infection.¹⁹² Blood streaking in the sputum is a frequent finding and may be chronic. Massive hemoptysis (>240 mL blood in 24 hours) presents in approximately 5% of patients during their lifetime.¹⁹⁴ Due to the strong correlation between hemoptysis and exacerbations of lung infection, initial treatment should include antibiotic therapy and rest from chest physiotherapy. Typically, aerosol therapies are temporarily held and measures to promote clot stabilization are considered. There are anecdotal reports of the use of the antifibrinolytic, tranexamic acid.¹⁹⁵ Beta blockade has also been reported to be helpful in acute and chronic hemoptysis presumably by reducing blood pressure and blunting the sympathetic response to coughing spells.¹⁹⁶ Although bronchoscopy can help to localize the site of bleeding, emergent bronchoscopy or radiographic imaging are of limited clinical utility. Often, emergent bronchial artery embolization (see eFig. 47-4F and G) should be attempted without waiting for these measures. Advances in invasive vascular interventions and improved clinical management strategies have resulted in significantly reduced mortality, which was historically as high as 10% after massive hemoptysis.¹⁹⁷

ABPA has a lifetime incidence of 2% to 8% in CF patients, although a few small cohorts report an incidence rate as high as 20%, suggesting an environmental association.^{198,199} *Aspergillus* is a common environmental mold and is frequently recovered in sputum culture. Although up to 50% of patients with CF may demonstrate precipitating antibodies to *A. fumigatus* in their serum, an IgE-mediated allergic hypersensitization must develop to manifest ABPA clinically.²⁰⁰ Clinical features include increased cough, dyspnea, wheezing, and the expectoration of rusty brown plugs containing many eosinophils. Radiographic findings can be present, including characteristic finger-in-glove pattern. Atelectasis and volume loss may also result from hyphae-laden mucoid impaction in segmental bronchi. A diagnosis of ABPA is made by fulfilling major and minor criteria that include characteristic clinical findings plus skin test hypersensitivity, elevated total IgE, and elevated levels of IgG and IgE antibodies against *A. fumigatus* or other fungi.¹⁴⁷ (See Chapters 38 and 48.)

Staphylococcal and pseudomonal empyemas have been described in patients with CF, but respiratory tract infections usually spare the pleural space, making complications such as *pleural effusions* and *empyema* uncommon. Nonetheless, pulmonary exacerbations may often be accompanied by pleuritic-type pain.²⁰¹

Digital *clubbing*, which is caused by hyperplasia and hypertrophy of connective tissue and increased vascularity of the distal phalanges, appears in virtually all patients with advanced CF and is often present early in individuals with active lung disease. The cause of clubbing is unknown, but it is known to resolve following lung transplantation.²⁰² Its

severity generally correlates with the severity of lung disease.²⁰³ *Hypertrophic pulmonary osteoarthropathy* is a common clinical entity presenting with advanced CF lung disease in up to 15% of older adolescents and adults.¹⁷⁰ Radiographic evidence for periostitis may be present in up to 8% of subjects. The distal aspects of the tibia, fibula, radius, and ulna are the most commonly affected sites. Signs and symptoms include pain, bone tenderness, swelling, and warmth over the involved areas; however, some patients may not manifest clinical symptoms. Effusions are uncommon but may arise in adjacent joints. Pain with ambulation or following strenuous physical exercise is common.²⁰⁴ Hypertrophic pulmonary osteoarthropathy is exacerbated during periods of poor respiratory health and tends to subside with the resolution of pulmonary exacerbations. Its presence with end-stage lung disease may yield persistent clinical symptoms requiring chronic analgesic therapy. There are also rare instances of cutaneous vasculitis causing self-limited, painless, palpable purpura, typically involving the lower extremities.²⁰⁵⁻²⁰⁷

Respiratory failure is the greatest contributor to mortality and is the cause of death in 90% of CF patients. *Hypoxemia* is first seen during exertion or sleep and progresses with lung disease.^{171,208} *Hypercapnia* is a late finding reflecting advanced lung disease, which typically progresses with disease severity and worsens during pulmonary exacerbations. Pulmonary hypertension and cor pulmonale may develop late in the disease process, resulting in hepatic congestion and peripheral edema.²⁰⁹ The role of pulmonary hypertension in CF is currently being studied to prioritize treatment regimens.²¹⁰ Hypoxemia, if not recognized or adequately treated, will contribute to worsening pulmonary hypertension and cardiac failure. Pneumothorax, hemoptysis, and infections such as respiratory syncytial virus or influenza can cause acute respiratory failure that is reversible with aggressive treatment.^{211,212}

GASTROINTESTINAL MANIFESTATIONS

Meconium ileus is seen in about 15% of newborns and is pathognomonic for CF. Failure to pass thick inspissated meconium in the first 48 hours of life is associated with abdominal distention and rapidly advances to bilious emesis. Affected infants are at risk for intestinal perforation and peritonitis accompanied by shock. Radiographic features are typical of high-grade bowel obstruction revealing multiple dilated loops of intestine and air-fluid levels (eFig. 47-9). A granular appearance of the lower abdomen may be noted due to accumulated meconium containing small air bubbles. The colon is characteristically small when visualized with contrast imaging (eFig. 47-10). Scrotal and peritoneal calcification can be seen following ileal perforation in utero. Meconium obstruction in the colon may only delay passage of stool. This has been termed the *meconium plug syndrome* and is much less specific for CF.²¹³

Beyond the newborn period, 20% of patients may develop the *distal intestinal obstruction syndrome* (DIOS). This is characterized by obstruction in the cecum, proximal colon, or terminal ileum associated with voluminous, viscous, and incompletely digested intestinal contents and is similar to meconium ileus (eFig. 47-11). Partial obstruction may manifest as a chronic or recurrent entity with intermittent

crampy abdominal pain as the only symptom. Fulminant complete obstruction is associated with failure to pass stool, resulting in abdominal distention and vomiting that may be bilious or fecal if allowed to progress. A mobile right lower quadrant mass may be palpable. Risk factors for DIOS include previous episodes, dehydration, dietary change, immobilization, bacterial overgrowth, treatment with antibiotics, and constipating medications. Other causes of acute abdominal pain with obstruction should also be considered, including intussusception, intestinal adhesions from previous abdominal surgery, and appendicitis, which may be partially suppressed due to concurrent antibiotic therapy. Appendicitis is thought to be uncommon in CF, with a 2% lifetime risk compared with a 7% to 8% risk in the general population.²¹⁴ Nonfilling of the appendix with contrast enema is seen in patients with CF; radiographic and histologic findings of a dilated, mucus-filled appendix are typical features,^{215,216} although the uninflamed appendix is frequently enlarged at CT in CF patients (eFig. 47-12). The loss of pancreatic and bowel secretion of bicarbonate to buffer gastric acid may result in duodenal irritation and recurrent epigastric pain.²¹⁷

Gastroesophageal reflux is common in CF; increased abdominal pressure associated with obstructive lung disease contributes to its high prevalence.²¹⁸ Consideration of gastroesophageal reflux is important because it can impair nutritional status and may contribute to microaspiration, accelerating lung disease. The presence of gastroesophageal reflux has been associated with worsened outcome after lung transplantation, and therefore patients with CF considered for lung transplantation should be evaluated thoroughly; some centers advocate surgical therapy for ongoing reflux during the peritransplant period.²¹⁹

Rectal prolapse develops in nearly 20% of children with CF but is an infrequent event for adults.²²⁰ Rectal prolapse in a child should raise consideration of CF even if it is the only obvious clinical symptom. Rectal prolapse is precipitated by the presence of bulky, sticky stools that adhere to rectal mucosa, poor nutritional status with loss of the perirectal fat that normally supports the rectum, and the presence of high intra-abdominal pressure due to frequent paroxysmal coughing.

PANCREATIC DISEASE

Exocrine pancreatic insufficiency (PI), due to intraluminal obstruction with thickened, dehydrated secretions, is present from birth in 85% of patients with CF.^{221,222} Adequate exocrine pancreatic secretion is present in 10% to 15% of patients and has defined genotypic associations. Insufficient release of pancreatic enzymes into the gut results in impaired fat and protein digestion and impaired absorption in the small bowel. Pancreatic insufficiency results in frequent bulky, greasy, foul-smelling stools and protuberance of the abdomen due to increased intraluminal bacterial gas production. Assessment of pancreatic function by ELISA measurement of stool fecal elastase-1 may enhance clinical assessment of PI.²²³

Untreated malabsorption results in nutritional failure and ultimately failure of linear growth, which has been linked to worsened outcomes.²²⁴ Patients with CF also grow slowly because of factors beyond nutritional intake and

intestinal absorption. For example, increased expenditure of energy to accomplish the work of breathing may be an important contributor; systemic inflammation may also play a role.²²² Fat-soluble vitamin deficiency was historically a common association at diagnosis in young children presenting with nutritional failure but is much less common in the era of newborn screening.

Symptomatic pancreatitis develops in less than 1% of adolescent or adult CF patients, usually in patients who have at least some residual exocrine pancreatic function.²²⁵ However, recurrent pancreatitis has been reported in association with CFTR dysfunction and can be the presenting feature of the disorder.^{24,226} Complete fatty replacement of the pancreas is common at CT (eFig. 47-13), and pancreatic lipomatosis and fibrosis are characteristic of pediatric CF. Pancreatic ductal dilation and calcifications may also be seen in CF patients. Rarely, there may be cystic replacement of the pancreas, referred to as *pancreatic cystosis*.

HEPATOBIILIARY DISEASE

Although relatively common, there is not yet consensus on the definition of CF-associated liver disease. Histologically, liver disease manifests as focal biliary cirrhosis and produces clinically significant liver disease in a greater proportion of CF patients as longevity increases. One description of clinically significant disease includes the constellation of an abnormal physical exam, abnormal liver function testing, and imaging findings.²²⁷ Liver disease may present as hepatosplenomegaly or as persistent elevation of hepatic enzymes (AST, ALT, bilirubin, GGT). Current guidelines recommend evaluation for liver disease when enzymes are elevated more than 3 times normal or remain 1.5 to 3 times normal for 3 months. Patients with CF-associated liver disease rarely develop acute fulminant hepatic failure but with advanced cirrhosis can develop portal hypertension and clinically significant esophageal varices.²²⁸ Steatosis is a common clinical finding and has been associated with malnutrition, essential fatty acid deficiency, and/or oxidative stress.²²⁷ Ultrasound is generally used to monitor severity and is currently being studied in longitudinal studies.

Biliary tract disease is common in CF. Cholelithiasis develops in approximately 10% of patients but causes significant clinical symptoms in less than 4% of cases.²²⁹ Formation of stones is encouraged by the abnormal ion transport environment resident in the gallbladder. A small or microgallbladder is seen in 20% to 30% of patients and is of unknown clinical significance.²³⁰

GENITOURINARY TRACT ABNORMALITIES

The vas deferens is congenitally absent in almost all males with CF.²³¹ Semen analysis is typically required to identify the 1% of male CF patients who are fertile. The volume of ejaculate is usually one third to one half of normal; complete absence of spermatozoa in addition to a number of chemical abnormalities that reflect absence of secretions from the seminal vesicles is usually apparent.²³² An increased incidence of inguinal hernia and hydrocele has also been reported.

Although significantly less common, female infertility in CF may be as high as 20%.²³³ Many women with CF and

advanced lung disease and/or malnutrition are anovulatory. Another obstacle to conception is the presence of thick tenacious cervical mucus and an increased presence of endocervicitis. This dehydrated mucus also has abnormal electrolyte concentrations, preventing the usual ferning at midcycle. As a result, this mucosal abnormality is thought to impede normal sperm migration.²³³ Urinary incontinence can be seen beginning in adolescence and does not clearly correlate with disease severity; rather, incontinence probably reflects chronic cough and increased abdominal pressure due to airflow obstruction.²³⁴

Pregnancy in females with CF appears to be increasing as clinical outcomes have improved. A longitudinal study of 325 pregnant women with CF demonstrated 258 live births (79%) and 67% therapeutic abortions.²³⁵ Compared with 1142 age- and severity-matched controls, pregnancy in a woman with CF did not have an independent negative effect on pulmonary status or mortality over 2 years.²³⁶ Successful pregnancy and delivery is possible and may be carried out safely, but it is essential that women with CF consider implications to their health as they consider family planning. Successful breast feeding has been reported in women with CF.²³⁷

SWEAT GLAND DYSFUNCTION

Sweat chloride is elevated in most CF patients due to abnormal chloride reabsorption in the sweat duct due to the absence of CFTR. This may predispose individuals with CF to excessive salt loss in certain settings. Young children are especially susceptible to depletion, especially when exposed to warm arid climates, or when there is additional salt loss due to vomiting or diarrhea. Typically children in this circumstance present with lethargy, anorexia, and hypochloremic alkalosis and/or hyponatremia.²³⁸

TREATMENT

OVERVIEW

Considerable progress in the understanding of CF lung disease and a concerted effort to address disease manifestations in a comprehensive fashion have led to a number of new therapeutic approaches to the disease.¹⁵ Therapies including mucolytics,²³⁹ hydrators of the airway surface,^{240,241} inhaled antimicrobials,²⁴²⁻²⁴⁴ systemic anti-inflammatory treatments,²⁴⁵⁻²⁴⁷ and nutritional support are the mainstays of current CF treatment (Table 47-4). These sorts of supportive therapies, in addition to comprehensive care undertaken at organized CF clinical centers, are responsible for the steadily improving life expectancy observed over the past decade (Fig. 47-10), resulting in a median life expectancy of 41 years in 2012, based on the latest analysis of the U.S. registry.²⁴⁸ Similar improvements have been observed in other developed countries. More recently, the first treatment that addresses the basic defect in CF by restoring CFTR function in patients with the G551D CFTR gating mutation has been approved, resulting in marked improvements among individuals with this mutation.²⁴⁹ Other therapies that address more common CFTR alleles or aim to replace CFTR with gene therapy are in

various stages of clinical development and promise to open a new therapeutic era in the disease (Fig. 47-11).

MONITORING AND AGGRESSIVE APPROACH

Aggressive monitoring and treatment of pulmonary infections and other common CF complications has been a key advance that is believed to have contributed significantly to improved clinical outcomes in the past decade.^{167,250,251} As

discussed earlier, the predominant lower airway pathogen changes through the lifetime of CF patients, with *S. aureus* and *H. influenza* being the most common organisms isolated during infancy and early childhood, while *P. aeruginosa* typically becomes the dominant pathogen later in the disease.²⁵² (See Fig. 47-9.) New attention has focused on the efforts to delay or prevent chronic colonization with *P. aeruginosa*, with a number of studies evaluating various regimens to best achieve sustained clearance. Coincident with this approach is increased attention to infection control to prevent acquisition of virulent organisms, particularly in health care settings where risk of acquisition is significant. Segregation of clinics by *Pseudomonas* status can reduce acquisition of epidemic organisms; standard infection control procedures alone may not be sufficient,^{253,254} leading to even more rigorous guidelines for patient isolation and prevention against comingling.²⁵⁵ Once established, *P. aeruginosa* is challenging to eradicate with antimicrobial therapy alone,^{74,256-259} although it can be accomplished in selected patients.¹²² Chronic colonization with *Pseudomonas* is associated with a more rapid decline in respiratory status,^{105,115,260} although not as severely as more virulent organisms such as *B. cepacia*^{261,262} or *B. dolosa*,²⁶³ which can also be associated with outbreaks due to nosocomial spread. As with chronic infection, early and aggressive nutritional therapy, particularly among young children with CF, has been crucial to achieving improved outcomes. Despite advances in lung function and delays in *Pseudomonas* growth, delaying the progression of CF in the adolescent years remains a challenge.

Sponsored in part by the CF Foundation, U.S. centers have embarked on a rigorous quality improvement program to facilitate best practices in CF care. Outcomes are compared between centers and made publically available to

Table 47-4 Cystic Fibrosis Therapeutics by Category	
Agent	Predominant Mechanism of Action
Restoration of Airway Surface Hydration	
Hypertonic saline*	Osmotic increase of airway hydration; expectorant
Mannitol†	Osmotic increase of airway hydration; expectorant
Mucolytics	
Dornase alfa	Cleaves DNA polymers
Anti-Inflammatory	
Ibuprofen	Reduce airway inflammation
Anti-Infectives	
Inhaled tobramycin	Chronic treatment of <i>Pseudomonas aeruginosa</i>
Inhaled aztreonam	Chronic treatment of <i>P. aeruginosa</i>
Dry powder tobramycin	Chronic treatment of <i>P. aeruginosa</i>
Azithromycin	Anti-inflammatory/anti-infective for chronic <i>P. aeruginosa</i> infection
Nutritional Therapies	
AquADEKs	Restore fat-soluble vitamin levels
Pancrelipase	Restore pancreatic enzyme levels

*Therapy commonly used but not FDA approved.

†Therapy only approved in Europe, Australia, and New Zealand.

Figure 47-10 Median predicted survival in CF. Median predicted survival for CF patients in U.S. Cystic Fibrosis centers in the CF registry from 2012. Data are depicted as medians for 5-year time spans from 1986–2012. Since the mid-1980s, predicted survival has increased from about 27 years of age to older than 36 years of age for the most recent 5-year time span. (Data from the Cystic Fibrosis Foundation Patient Registry, Bethesda, MD; 2012.)

Figure 47-11 CF therapeutics by category. This figure depicts the mechanisms of CF airway pathology. CF therapeutics attempt to address defective CFTR function by gene therapy or modulation of CFTR expression or function; to address the diminished airway surface liquid, abnormally viscous mucus, and disrupted mucociliary clearance; and finally, to address chronic airways infection and inflammation. When respiratory failure develops, lung transplantation is the remaining option.

encourage continuous improvement.²⁶⁴ A culture of cooperation among centers, patients, families, and the Cystic Fibrosis Foundation has led to evidence-based guidelines, protocol-driven therapies, and rapid dissemination of results to facilitate advances in health care delivery.²⁶⁵

CFTR Potentiators, Correctors, and Other Treatments for the Basic Defect

On the basis of functional consequences of various *CFTR* mutations, specific therapeutic strategies to restore deficient or defective protein function are being developed by altering *CFTR* expression or function (Fig. 47-12 and Table 47-5). Because of ambitious high-throughput screening efforts,^{58,266-269} the benefits of these new *CFTR* modulators have begun to come to fruition for CF patients. Results in the clinic demonstrate that the rescue of the *CFTR* protein by the archetype *CFTR* modulator ivacaftor is associated with marked improvements in the clinical outcome that compare favorably with previous therapies widely used by CF patients.^{249,270,271} The *CFTR* potentiator ivacaftor (formerly VX-770) was the first to advance as an approved CF treatment among patients with the G551D gating mutation, an allele represented in approximately 4% of CF patients. ***CFTR* potentiators** function to activate *CFTR* channels located at the cell surface. They potentiate cAMP-mediated channel gating via decoupling with ATP hydrolysis^{58,272,273} and may be more broadly useful against a greater variety of *CFTR* missense alleles, including other class III gating mutations and other *CFTR* forms that exhibit residual activity at the cell surface (i.e., conductance and mild processing mutants).^{274,275} The highly efficacious treatment benefit observed with ivacaftor therapy has engendered considerable interest toward recapitulating its effects among other more common *CFTR* alleles.²⁷⁶ This includes correctors of F508del *CFTR* misfolding, termed *CFTR* correctors. ***CFTR* correctors** attempt to restore normal *CFTR* processing to the most common *CFTR* mutation. Other agents that induce readthrough (or suppression) of PTCs to induce expression of full-length *CFTR* are also under development and have shown promise in proof-of-concept clinical

trials.²⁷⁷⁻²⁸⁰ Other approaches beyond these small molecule *CFTR* modulators are also being explored. For example, gene replacement by viral and nonviral gene therapy remains an approach under active investigation,²⁸¹ as well as newer strategies that attempt to express *CFTR* through transduction of mRNA alone.^{282,283} In total, this class of agents that target the basic CF defect serves as both a prime example of the potential for new genetic-based approaches in CF and a seminal example for other genetic diseases. Because many patients (~40%) are complex heterozygotes for more than one *CFTR* mutation,²⁸⁴ combination therapeutics addressing more than one *CFTR* allele or use of multidrug therapy seem likely in the future and will dictate a need for individualized therapeutics optimized for particular patients on the basis of their underlying disease and other genetic covariates.²⁷⁶

***CFTR* Potentiators.** *CFTR* potentiators activate mutant *CFTR* localized to the cell surface by potentiating channel gating stimulated by physiologic activation of cyclic AMP.^{58,269,285-287} The impetus for development included the anticipated need to activate F508del *CFTR* once localized to the cell surface, in addition to the need to activate other mutant channels that reside at the plasma membrane but are dysfunctional due to aberrant gating, impaired conductance, or a reduced number of channels due to mild processing mutations or splice variants. Early attempts included use of genistein, a natural flavonoid molecule that demonstrates strong activation of *CFTR* but is poorly absorbed and exhibits other undesirable physiologic properties.^{286,288,289} Subsequently ivacaftor and other investigational *CFTR* potentiators were discovered via high-throughput screening approaches that identified small molecule potentiators optimized for druglike qualities through traditional medicinal chemistry approaches.^{58,269,285-287} Ivacaftor induced about 50% *CFTR* activity in G551D/F508del *CFTR*-expressing primary epithelial cells, an emerging benchmark for preclinical development of *CFTR* modulators.⁵⁸

In a long-term Phase III placebo-controlled trial conducted in older children and adults (age 12 and older) with

Figure 47-12 CFTR modulators by mutation class. Classes of defects in the *CFTR* gene include premature termination codons (PTCs) causing truncated protein translation (class I); misfolded CFTR, including deletion of phenylalanine at position 508 (class II, location shown with a red dot); full-length CFTR that reaches the cell surface but exhibits abnormal channel gating (class III; ATP hydrolysis is disrupted, at site identified in red) or reduced pore conductivity (class IV); and full-length CFTR with splicing errors (class V); premature termination codon suppressors (e.g., aminoglycosides, ataluren) bind to ribosomal subunits (green star) to allow suppression of PTCs and expression of full-length protein. Class II mutations like F508del can respond to small-molecule corrector compounds to restore folding defects and/or enhance expression of the channel at the cell membrane (e.g., lumacaftor, VX-661). Without correction, almost all class II CFTR is sent to the proteasome, leaving detectable surface protein in only rare individuals. CFTR potentiators include ivacaftor (green chevron) for patients with *CFTR* gating mutations. Future directions include exploring the use of CFTR potentiators for other mutant CFTR known to reside at the cell surface, such as noncanonical splicing mutations. Combination therapy with potentiators has also been proposed for classes I and II *CFTR* mutations. (Adapted from Rowe SM, Borowitz DS, Burns JL, et al: Progress in cystic fibrosis and the CF Therapeutics Development Network. *Thorax* 67(10):882–890, Fig. 1, 2012.)

Table 47-5 Approved and/or Investigational Therapeutics Targeting Each *CFTR* Mutational Class

CFTR Modulator Class	Representative Molecules	CFTR Mutations Affected	CFTR Mutation Class
Potentiator	Ivacaftor (VX-770)	G551D, non-G551D gating mutations*, other surface localized <i>CFTR</i> alleles*, F508del <i>CFTR</i> [†]	Class III Possibly classes IV, II, and I
Corrector	Lumacaftor (VX-809), VX-661, N6022 (N30 Pharma)	F508del*	Class II
Premature termination codon suppressor	Ataluren (PTC124), aminoglycosides	Nonsense mutations	Class I
Splicing repair	Antisense oligonucleotides	Splicing mutations*	Class V

*Investigational.

[†]In combination with a *CFTR* corrector.*CFTR*, cystic fibrosis transmembrane conductance regulator.

CF and with at least one copy of the G551D-*CFTR* mutation, ivacaftor caused a roughly 10% absolute improvement in FEV₁ at 24 weeks, an effect durable through 48 weeks of testing, providing confirmation of prior Phase II testing.²⁴⁹ In addition, all secondary clinical end points showed meaningful and statistically significant improvements, including a 55% reduction in the probability of experiencing a pulmonary exacerbation, improved weight gain, and an improvement in respiratory symptoms. Sweat chloride testing also exhibited marked improvements (mean of sweat chloride was about 55 mEq/L, a value below the traditional diagnostic threshold). Of note the improvement in spirometry was rapid; within 2 weeks, 90% of the maximal improvement was observed, suggesting that the mechanism was clearance of mucus, rather than the reversal of longstanding structural lung disease. In a smaller study that enrolled pediatric G551D CF patients 6 to 12 years old,²⁷¹ benefit was also documented by lung clearance index measurements in CF patients with minimal detectable lung function abnormality by spirometry, likely reflecting activity in the small airways.²⁹⁰ The degree of improvement in spirometry among participants of the Phase III trial of ivacaftor compares favorably with that of commonly used therapies for chronic CF care, including inhaled recombinant human DNase,²³⁹ inhaled tobramycin,²⁴² azithromycin,²⁴⁶ and hypertonic saline.²⁴⁰ In all clinical studies to date, ivacaftor appeared safe and well tolerated, although monitoring of liver function tests is recommended.²⁹¹

In contrast to the large effect in G551D patients, ivacaftor monotherapy had no meaningful effect in CF patients homozygous for F508del *CFTR*, establishing that *CFTR* potentiation alone is unlikely to be effective without concomitant administration of a corrector molecule to bring F508del *CFTR* to the cell surface.²⁹²

These findings have formed the basis of clinical approval for ivacaftor in CF patients with G551D mutations, and this treatment has rapidly been deployed to children and adults with the appropriate mutation. Establishing the proof of concept that *CFTR* modulation could have pronounced clinical effects among CF patients has also engendered considerable interest in extending these findings toward other *CFTR* mutations in which ivacaftor might be effective and developing *CFTR* modulators for other common *CFTR* alleles.^{274,275} The long-term benefit of effective modulation of *CFTR* will also be evaluated in ongoing

long-term observational studies, which will examine the effects of ivacaftor in G551D CF patients on clinical outcome, sputum microbiology, and systemic inflammation, among other parameters.

Because ivacaftor also increased *CFTR* activity in other gating mutations in vitro,²⁷⁵ these non-G551D gating mutations were also tested; the beneficial effects of ivacaftor were also observed in patients with other non-G551D class III gating mutations. Patients observed a large increase in FEV₁ and similar decrease in sweat chloride compared with that seen in patients with G551D, suggesting a class effect. Other *CFTR* mutations, such as conductance mutations, mild processing mutations, or *CFTR* splice variants allow low levels of partially active *CFTR* channels to reach the cell surface, conferring partial *CFTR* function²⁷⁴ and typically a milder CF phenotype. The effect of ivacaftor on partially active missense mutations from these *CFTR* classes is generally proportionate to basal *CFTR* function, reflecting the ability of increased gating to compensate in part for reduced surface expression or conductance, even when gating is normal in these *CFTR* forms.²⁷⁴ With this information in mind, ivacaftor is being tested in the archetype conductance mutation R117H in addition to individuals who exhibit residual *CFTR* function and a relevant *CFTR* allele. These results may justify use of *CFTR* potentiators in a broader group of individuals with CF. Combined with individuals with gating mutations, this represents approximately 10% to 15% of the CF population who ultimately might benefit from monotherapy with a *CFTR* potentiator.

CFTR Correctors. Significant effort has been directed toward the goal of correcting the folding of F508del *CFTR*, thus restoring ion channel activity to the misfolded protein. Early attempts include the evaluation of agents such as 4-phenyl butyrate to down-regulate HSC70 (or other protein processing chaperones), a pathway central to the protein folding process that has been shown to augment F508del *CFTR* expression in vitro and represent an early example of compounds tested in the clinic.^{293,294} Curcumin and 8-cyclopentyl-1,3-dipropylxanthine are examples of F508del *CFTR* processing correctors that did not successfully translate from in vitro studies to clinical results.²⁹⁵⁻²⁹⁷ More recent efforts have resulted from high-throughput library screens for chloride channel function following incubation of test compounds with F508del expressing cells.^{267,269,298} A number of these strategies have identified

F508del correctors that may address cell biogenesis through chaperone pathways. Pharmacologic activity of such agents has also been reported to augment F508del CFTR half-life in the plasma membrane through altered surface recycling attributed to features of the cellular processing machinery²⁹⁹ or reduced endocytic trafficking.³⁰⁰ This class of agents may be potential drug development candidates if their safety in vivo is confirmed. Other compounds have been shown to directly interact with CFTR^{301,302} and may offer greater specificity than agents that alter general aspects of cell folding or cellular quality control.

Success toward effective correction of F508del CFTR was seen during initial Phase II testing of lumacaftor (formerly VX-809), a putative F508del CFTR corrector. Results demonstrated modest decreases in sweat chloride compared with placebo but were not accompanied by improvements in spirometry or other clinical measures.³⁰³ Although this established that rescue of F508del CFTR in human subjects is achievable by a systemically delivered small molecule, the degree of CFTR rescue was insufficient to confer clinical improvement. Because F508del CFTR also exhibits abnormal channel gating, in addition to aberrant cellular processing, an approach to address insufficient activity is to coadminister a CFTR potentiator with a CFTR corrector.³⁰⁴ This approach is substantiated by in vitro results demonstrating that combination therapy increased CFTR function in F508del CFTR homozygous HBE cells.³⁰⁴ Recently a Phase II trial demonstrated that coadministration of lumacaftor and ivacaftor resulted in significant improvements in FEV₁ (≈6% treatment effect), although changes in sweat chloride did not correlate with additional benefit seen following addition of the potentiator.^{304a} Lesser effects were observed in CF patients heterozygous for F508del CFTR, providing evidence of a gene dose effect. The potential benefit of ivacaftor and lumacaftor in combination among F508del homozygous CF patients is presently being pursued in two large international Phase III trials. If positive, results could justify use of corrector-potentiator combination therapy for the most common CFTR mutation. An alternative corrector, VX-661, which has a similar mechanism as lumacaftor but more advantageous pharmacologic properties, also demonstrated additive benefit when used in combination with ivacaftor in individuals homozygous for F508del CFTR alleles in Phase II testing, providing additional confidence that the combination of corrector and potentiator agents could be effective among individuals expressing F508del CFTR. The results also suggest that ivacaftor may be useful to augment the rescue of other mutant forms of CFTR, such as premature termination codons or other processing mutants (e.g., class II mutations) sensitive to the effects of CFTR correctors.

Other strategies to identify agents that augment F508del CFTR folding are also being developed, and interest has accelerated with recent successes in clinical studies. Using a trafficking assay based on epitope-tagged CFTR, phosphodiesterase inhibitors including sildenafil and other active analogues have been shown to improve surface localization of the mutant protein. The same agents augment short-circuit current in F508del CFTR-expressing cell lines³⁰⁵ and enhance NPD in CF mice,^{306,307} as did the related compound vardenafil.³⁰⁸ Because misfolded F508del CFTR exhibits two fundamentally distinct properties that alter its processing

(namely nucleotide binding domain 1 stability and interdomain assembly), it has subsequently been recognized that compounds that address these mechanisms independently can exhibit additive or synergistic effects of correction of F508del CFTR misfolding. Moreover, the global cellular response to misfolded protein may also represent a target. For example, treatment of CF cells with *histone deacetylase* (HDAC) inhibitors can modulate ER stress, and HDACs such as *suberoylanilide hydroxamic acid* (SAHA), as well as siRNA-silencing, increase levels of F508del CFTR in the cell membrane.³⁰⁹ Additive or synergistic rescue of F508del CFTR using more than one such strategy may offer hope of achieving ion transport activity sufficient to confer a normal phenotype in CF respiratory epithelia.^{298,310}

Translational Readthrough. Readthrough of *premature termination codons* (PTC) represents a potential approach to address CF caused by this mechanism, which could also be applicable to many other genetic disease caused by nonsense mutations. The approach was identified when certain aminoglycoside antibiotics were found to interact with the eukaryotic rRNA within the ribosomal subunits.³¹¹ Through this interaction, the fidelity of eukaryotic translation can be altered by interrupting the normal proofreading function of the ribosome.³¹²⁻³¹⁸ Insertion of a near cognate *amino acid* (AA) at a PTC allows protein translation to continue normally.³¹⁴ Specificity is conferred by greater termination codon fidelity at the authentic (3') end of mRNA and has been established in vitro by demonstrating that there is no detectable elongation beyond native termination codons.³¹⁹⁻³²² This has been bolstered by a good safety profile in both preclinical and clinical studies and has subsequently been adopted in a number of relatively common genetic diseases aside from CF in which premature termination codons are relatively prevalent, including Duchenne muscular dystrophy,³²³⁻³²⁵ Hurler syndrome,^{67,81,82} ceroid lipofuscinosis,³²⁶ nephropathic cystinosis,³²⁷ and expression of mutated p53.³²⁸

Proof of concept experiments with aminoglycosides established that PTCs within CFTR in human subjects can be suppressed, resulting in the synthesis of full-length, functional CFTR protein.^{319-322,329} The approach has also demonstrated success in mouse models of CF.^{330,331} Following two small pilot trials indicating restoration of chloride secretion in CF subjects harboring PTCs,^{320,322} a double-blind, placebo-controlled trial conducted in Israel showed correction of nasal ion transport specifically in subjects with nonsense mutations following topical administration of gentamicin, and as expected, not in CF controls homozygous for F508del.³²¹ A trial examining systemic gentamicin in seven French subjects with Y122X CFTR, a mutation highly susceptible to readthrough, also indicated rescue of CFTR activity in the airway and sweat duct.³¹⁹ Not all aminoglycoside trials in CF have demonstrated success, suggesting low levels of protein correction. Regardless, due to the known toxicity and poor bioavailability of aminoglycosides, more efficacious agents that avoid undesirable properties of aminoglycosides will be needed for the long-term genetic treatment of CF. One promising approach uses medicinal chemistry optimization to identify the antimicrobial, toxic, and readthrough effects of aminoglycoside scaffolds, a strategy demonstrating initial success using in vitro

reporters of efficacy and toxicity,³³² and cell- and animal-based models of CFTR rescue.³³³

Others have attempted to identify novel compounds that address the disadvantages of aminoglycosides. One such molecule is ataluren (formerly PTC124), an investigational agent resulting from high-throughput screening efforts to identify molecules that induce translational readthrough.³³⁴ Ataluren is an orally bioavailable agent^{330,335} that has demonstrated efficacy in vivo in a transgenic mouse model of nonsense-mediated CF.³³⁶ The drug is well tolerated in normal and CF subjects,^{335,337} leading to a series of clinical trials examining ataluren in CF individuals harboring nonsense alleles. Results thus far have been mixed. Two studies, conducted in Israel among adults²⁷⁸ and France/Belgium³²⁹ in pediatric subjects, detected rescue of CFTR activity (as detected by the NPD) in open-label, two-dose crossover Phase II trials in CF subjects possessing at least one premature termination codon. The former study included follow-up testing that examined the effect of ataluren for 3 months in 19 subjects previously studied for 2 weeks; significant and time-dependent improvement in CFTR activity following the treatment period were observed.³³⁸ In contrast, a nearly identical trial conducted in the United States did not demonstrate improvement in CFTR function,³³⁹ raising questions about efficacy. Subsequent Phase III testing conducted over 1 year was negative, although a trend toward improved FEV₁ and exacerbation frequency was observed, which was statistically significant in a subgroup of individuals not exposed to inhaled tobramycin, a concomitant medication later shown to attenuate the beneficial effect of ataluren in vitro.³⁴⁰ Future studies will evaluate the effect of ataluren in CF subjects with nonsense mutations that are not exposed to tobramycin. The effects of ataluren are likely also modulated by genetic founder effects including the degree of *CFTR* mRNA expression at baseline as modulated by nonsense mediated decay.^{278,341} Poor selection and optimization of ataluren efficacy has also been suggested to have affected successful development of this agent, due in part to its stabilization of firefly luciferase,³⁴² which induces a paradoxical and off-target increase in the reporter assay used to select the agent.³⁰⁹ More recent studies have highlighted its relatively poor activity.³⁴³ Given new knowledge regarding the best models to identify and optimize CFTR drug candidates that has emerged since the identification of ataluren, it is possible that identification of new chemicals using alternate readthrough assays might yield more efficacious compounds.

Gene Therapy

Nasal administration of *CFTR* gene transfer agents rescued CFTR-dependent Cl⁻ transport in proof-of-concept trials, but variable efficiency of vectors coupled with heterogeneous transgene expression and adverse effects from inflammation have dampened enthusiasm. With NPD as an outcome, viral vectors have demonstrated transgene delivery using adenovirus^{344,345} and *adeno-associated adenovirus* (AAV),³⁴⁶ but positive results have not been universal.³⁴⁷ Failure of a pulmonary AAV technology diminished enthusiasm in the United States. Improvements in Cl⁻ transport using lipid-based gene transfer vectors were initially limited to small and questionable changes³⁴⁸⁻³⁵⁰ or improvements in specific subgroups.³⁵¹⁻³⁵³ More recent preparations have

demonstrated somewhat improved transfer³⁵⁴⁻³⁵⁶ but have been hampered by concerns regarding safety and consistent expression. Several technologies including compacted DNA nanoparticles^{357,358} or depletion of immunogenic CpG motifs have shown promise toward improving delivery. The latter is the basis of the lead vector employed by the U.K. gene therapy consortium, which is currently being evaluated in a large and long-term clinical trial.³⁵⁸ Newer viral transfer technologies that promise sustained gene expression are also under development.³⁵⁹

Splicing and Other RNA Repair

Splicing mutation represents a relatively common minority of *CFTR* alleles. For example, the 10th most common CF mutation is 3849+10kb C-to-T, which leads to inclusion of an 84-base pair cryptic exon in the mature mRNA.³⁶⁰ This cryptic exon contains an in-frame nonsense codon, which leads to production of truncated nonfunctional proteins. Splicing machinery is heterogeneous both among patients and also among tissues within an individual, resulting in relatively heterogeneous expression of the disease. This forms the basis of examining the potential of a CFTR potentiator in individuals with relatively preserved CFTR expression due to reasonable levels of CFTR expression. The variation in splicing efficiency can also be exploited using antisense oligonucleotides to induce normal splicing by masking mutant splice sites. Although this would require specific antisense oligonucleotides to be developed for each *CFTR* splice mutation, recently use of such technology has shown therapeutic efficacy in Duchenne muscular dystrophy.³⁶¹ Thus, a similar approach in CF has been proposed, which could be combined with other CFTR therapeutics on an individual basis. Full-length RNA transduction has also been suggested for the treatment of genetic diseases and could be exploited in CF.

Insights on Disease Mechanism Revealed by CFTR Modulators

Effective modulation of CFTR function has provided a new opportunity to determine the disease pathogenesis, including heretofore unanticipated effects of CFTR. Although CFTR clearly functions as a chloride transporter on the epithelial surface, there is emerging interest in CFTR-mediated regulation of mucociliary clearance, and whether CFTR has important effects on the physical properties of mucus itself due to its role as a bicarbonate transporter and regulator of airway pH. This is supported by data that ivacaftor improves airway obstruction due to resolution of mucus plugging in susceptible airways as observed by He³ magnetic resonance imaging before and after ivacaftor administration in G551D CF subjects^{362,363} and also augments mucociliary clearance as observed by clearance of inhaled Tc99 radiolabeled particles. Colonization of *P. aeruginosa* also improves within 6 months, suggesting the possibility that innate defense is augmented simply by enhancement of CFTR function, before any improvement of structural lung disease. The relatively large magnitude of weight gain observed with ivacaftor in CF patients with G551D-*CFTR* has recently been attributed to its beneficial effect on intestinal pH via bicarbonate secretion, raising the possibility that mucosal integrity might also be improved throughout the gut. Other potential avenues for exploration include the

effect of CFTR modulation on other manifestations of CF, such as glucose metabolism, innate immunity and leukocyte function, osteopenia, pancreatic insufficiency, and gastrointestinal absorption, some of which may be directly tied to CFTR activity.

RESPIRATORY THERAPIES

Physical Airway Clearance

The combination of cough augmented with chest vibration or percussion to loosen mucus represents a cornerstone of the daily care of CF to reduce airway obstruction and prevent CF exacerbations.³⁶⁴ Daily clearance maneuvers including chest physiotherapy by vibropercussion, hand-administered therapy, or the chest physiotherapy vest clearance system, are considered standard of care, although the long-term benefit has not been systematically examined in randomized controlled trials.^{365,366} Rather, the benefits were established in a small trial of older children demonstrating improvements in FEV₁ and sputum production, which has been further supported by a series of nonrandomized trials.^{367,368} Alternative airway clearance techniques include *positive expiratory pressure* (PEP), “huff coughing,” and the use of vibratory flutter valves.³⁶⁸

Exercise therapy may have additive benefit to the physical maneuvers described earlier. Standardized, aerobic exercise programs targeting 70% to 85% of maximal heart rate have demonstrated benefits on exercise tolerance but do not improve lung function. Similar results are observed in isometric exercise programs.³⁶⁹ The role of supervised pulmonary rehabilitation programs in severe CF lung disease is currently being explored.³⁷⁰

Airway Rehydration Therapy

Efforts to rehydrate the ASL to augment mucociliary clearance have led to studies examining nebulized *hypertonic saline* (HTS). HTS improves airway hydration in CF models and causes a durable increase in mucociliary clearance in CF subjects.²⁴¹ A multicenter, randomized, placebo-controlled trial showed a modest improvement in pulmonary function and a 56% reduction in frequency of CF pulmonary exacerbation despite relatively poor compliance ($\approx 63\%$ at the end of the trial).²⁴⁰ Evidence suggests that the effects of HTS are additive to rhDNase.^{240,371,372}

The ISIS (*Infant Study of Inhaled Saline* in CF) trial examined the effect of HTS administration to young children with CF (ages 4 months to 5 years, before spirometry can be reliably conducted). Although this study did not demonstrate a benefit on the primary end point of rate of pulmonary exacerbations, the rate of these events was extremely low, limiting sensitivity.³⁷³ Nevertheless, a substudy of patients who underwent infant PFTs demonstrated significant improvements in FEV_{0.5}, a finding that will be tested using the Lung Clearance Index, an effort-independent measure of pulmonary obstruction. Until results are confirmed, HTS therapy is not recommended in this age group.¹⁵¹

Because a minority of subjects develops bronchospasm on administration of HTS, inhaled β_2 -agonist is generally recommended before HTS dosing; moreover, HTS should be used cautiously in those with severe pulmonary

obstruction. Many will exhibit excessive cough, limiting use, although this will often decrease with repeated administration.²⁴⁰

The use of nonabsorbable sugars, such as mannitol, to hydrate the airways by generating an osmotic gradient of fluid to the airway surface is an alternative to HTS. After success in early-phase trials,³⁷⁴ two large-scale clinical trials were recently conducted. Although the North American trial demonstrated a trend toward improved FEV₁ at 26 weeks of therapy, a parallel trial in Europe and Oceania demonstrated reduced exacerbations in the treatment arm.^{375,376} On the basis of this success, inhaled mannitol therapy is approved for CF patients older than 18 in Europe, Australia, and New Zealand, although intermediate results combined with a potential risk of hemoptysis have been a barrier to approval in the United States.

Dornase Alfa

Use of inhaled recombinant human DNase (dornase alfa), a pharmacologic treatment to improve the physical properties of mucus, has been shown to be beneficial in randomized, placebo-controlled trials in CF subjects and was among the first CF-specific medicines to be approved for respiratory disease. Dornase alfa causes dissolution of excess DNA debris that accumulates due to bacterial infection, mucus stasis, and the large influx of neutrophils into the airway lumen. Dornase alfa has improved pulmonary function, frequency of pulmonary exacerbation, and QOL.²³⁹ Trials examining dornase alfa therapy in individuals with severe pulmonary disease (FVC < 40% predicted) also show continued benefit.³⁷⁷ It also appears beneficial in mild disease; dornase alfa stabilized an increase in inflammatory markers in bronchoalveolar lavage fluid of young children³⁷⁸ and improved radiographic measures of gas trapping.³⁷⁹ Dornase alfa also improved ventilation inhomogeneity as determined by lung clearance index in pediatric patients with minimal decrement in spirometry.³⁸⁰ Thus, dornase alfa therapy is recommended for CF patients in all ranges of disease severity.³⁸¹

Inhaled Antibiotics

Chronic infection is a sine qua non of bronchiectasis, and aggressive antimicrobial therapy to curb or control chronic infection is a mainstay of chronic CF care. Because the inhaled route provides higher doses of antibiotics to the mucopurulent-filled airways, several antimicrobials are frequently used in chronic CF care and have been shown to improve lung function and reduce pulmonary exacerbations. Alternating use of chronic inhalational antibiotics is intended to target the airways while avoiding systemic toxicities and limiting emergence of bacterial resistance through continuous selection pressure. The first agent to be approved for this purpose was inhaled tobramycin, which has been shown to be associated with improved pulmonary function, reduced exacerbation rate, and increased weight compared with placebo when administered twice daily on alternate 4-week periods.^{151,382} Concerns about daily burden of therapy leading to patient nonadherence have led to the development of a dry powder formulation, which was shown to be noninferior to conventional nebulized tobramycin²⁴² and improved patient satisfaction when tolerated.

More recently, the inhaled monobactam aztreonam has been developed for chronic use in CF. Initial studies demonstrated improved QOL and prolonged gap between exacerbations.^{383,384} A large 6-month trial involving CF patients older than 6 who previously used inhaled tobramycin demonstrated improved FEV₁ and reduced exacerbations with aztreonam every other month³⁸⁵ compared with those assigned to continue every-other-month inhaled tobramycin. A similar study in subjects with milder lung function abnormalities demonstrated more modest improvements in FEV₁ and QOL.³⁸⁶ Thus, inhaled aztreonam is currently recommended for CF patients older than 6 with chronic *Pseudomonas* infection of all lung function ranges.³⁸⁷ Inhaled colistin is often used as an alternative antipseudomonal agent in subjects with resistant strains, although it is not FDA approved for this purpose and is associated with side effects such as bronchospasm.^{151,388,389}

It is not yet clear which antimicrobial is best for individual patients, but the choice of agent is generally driven by the dominant pathogen, antimicrobial resistance patterns, and patient preference because antimicrobial resistance does not always predict clinical response. Some clinicians, particularly in Europe, currently endorse a continuous alternating therapy approach using two or more inhalational antibiotics on the basis of the empiric finding that certain patients frequently exhibit exacerbations when off antibiotics. Formal investigation of this approach using continuous alternating 28-day cycles of inhaled tobramycin and aztreonam is presently under way. A number of other antibiotic regimens, generally derived from effective systemic antibiotics, are also under investigation and could provide additional options for long-term control of chronic respiratory infections. These include inhaled fluoroquinolones³⁹⁰ and vancomycin.³⁹¹ Whether suppression or eradication of *Staphylococcus* species, including MRSA, offer benefit is an open question. Of note, oral prophylaxis for *S. aureus* led to increased *Pseudomonas* infection in treated patients, warranting caution.³⁹²

Bacterial Eradication

The primary morbidity and mortality in CF is attributable to obstructive respiratory disease produced by chronic endobronchial infection with opportunistic bacteria. *P. aeruginosa* infection is clearly associated with decline in respiratory function, and early acquisition of *Pseudomonas* is associated with increased morbidity and mortality.^{105,393-398} Consequently, identification of infection and eradication via treatment with anti-pseudomonal antibiotics is believed to result in sustained lung function and delayed mortality.^{115,399} Furthermore, early isolates are present at lower density, are generally nonmucoid, and display favorable microbial resistance profiles, reflecting a “window of opportunity” for treatment and eradication.^{400,401} *Pseudomonas* infection becomes more prevalent with increasing age, with positive respiratory tract cultures reported in up to 30% of infants, 30% to 40% of children (2 to 10 years), and 60% to 80% of adolescents and adults.⁴⁰² Newborn screening for CF may allow earlier identification of *P. aeruginosa* infection in children before the onset of significant lung disease and the development of antimicrobial resistance that may limit the efficacy of therapy. Following detection of *P. aeruginosa* in asymp-

tomatic children, current opinion supports clinical intervention to eradicate the organism. Antimicrobial regimens differ from minimally invasive inhaled antibiotics to aggressive intravenous dosing.¹¹⁰ Although several studies have validated the efficacy of various treatment regimens, no treatment regimen has demonstrated clear superiority. Obstructive lung disease may limit efficacy of inhaled antibiotics. Successful eradication of other CF pathogens such as *B. cepacia* and MRSA has also been reported, but no conclusive standard eradication practice exists.

Macrolide Therapy

Although macrolide antibiotics do not exhibit significant antipseudomonal properties, the utility of these agents in diffuse panbronchiolitis, a rare disease that resembles CF (including chronic infection with *P. aeruginosa*), led to therapeutic trials in CF patients.⁴⁰³⁻⁴⁰⁶ In a multicenter, randomized, placebo-controlled trial, alternating-day oral azithromycin demonstrated improved pulmonary function that was accompanied by a large reduction in pulmonary exacerbations.⁴⁰⁷ Similar results were seen in a Canadian study using clarithromycin.⁴⁰⁸ Beneficial effects of azithromycin can also be observed in CF patients who are not chronically infected with *Pseudomonas* (through less well-described anti-inflammatory effects), further suggesting that the mechanism is independent of antimicrobial properties; a large clinical trial demonstrated improved rates of exacerbation,⁴⁰⁹ although improved FEV₁ was not observed. On the basis of current evidence, the present guidelines assign a lower priority for chronic azithromycin in noninfected patients.²⁴⁵ The rising incidence of nontuberculous mycobacterial infections raises concern about the long-term use of azithromycin due to the potential for inducible macrolide resistance. Some in vitro data suggest increased risk of inducing atypical mycobacteria,¹⁵¹ although this has not been observed in epidemiologic studies.⁴¹⁰ Nevertheless, annual screening for atypical mycobacteria is recommended and is particularly important in azithromycin-treated patients. Safety and efficacy of azithromycin in young infants with CF at high risk for bronchiectasis as detected by elevated neutrophil elastase is currently under way.

Anti-inflammatory Therapy

Intense neutrophilic inflammation is characteristic of CF and remains a therapeutic target that has not been fully realized.^{140,411-413} Early trials utilizing chronic, alternate-day systemic corticosteroids showed a beneficial effect of prednisone (1 mg/kg) on lung function, but its use remains limited by steroid toxicities and is not recommended for routine use.⁴¹⁴⁻⁴¹⁶ Inhaled steroids have frequently been studied in small trials. In some studies, improved airway reactivity has been observed, but they have not demonstrated sustained effects on lung function and withdrawal can be tolerated without clinical deterioration.^{417,418} Use is generally limited to individuals with an asthmatic phenotype given the potential concern for bone demineralization, adrenal suppression, and growth retardation in pediatric patients.

A number of other anti-inflammatory molecules have been studied in CF, although the appropriate window where blockade of inflammation, which has both destructive and

beneficial anti-infective effects, is not yet clear. High-dose ibuprofen, a *nonsteroidal anti-inflammatory drug* (NSAID), has been shown to improve the rate of pulmonary function decline, but its beneficial effects were greatest in young children.⁴¹⁹ Confirmatory studies also demonstrated beneficial effects.^{247,420} Despite this evidence, NSAID therapy is not widely utilized in the United States due to concerns of chronic toxicities, particularly in older individuals, and the need for pharmacokinetic monitoring to achieve adequate serum levels.⁴²¹ For example, inadequate levels are associated with a paradoxical proinflammatory effect producing increased neutrophil migration.^{247,422}

Attempts to extend the observed benefits of anti-inflammatory therapy to other eicosanoid-active agents (e.g., leukotriene inhibitors) have been variable and include an increase in pulmonary complications with a nonselective LTB₄ antagonist.^{69,423} Along similar lines, aerosolized administration of interferon gamma-1 β was not effective in a randomized, placebo-controlled trial,⁴²⁴ nor were initial attempts to block proteases with inhaled antitrypsin.⁴²⁵ Other agents such as HMG Co-A reductase inhibitors, hydroxychloroquine, and methotrexate have not demonstrated convincing benefit, illustrating the challenge of successfully targeting this mechanism. Nevertheless, more therapies are under development and could circumvent problems if appropriate patient selection is considered.

OTHER SUPPORTIVE CARE

Pulmonary Exacerbations

Exacerbations of CF pulmonary disease are characterized by increased cough and sputum production, respiratory distress, diminished physiologic tolerance, weight loss, decreased spirometry, increased hypoxemia, or development of a major pulmonary complication such as hemoptysis.⁴²⁶⁻⁴²⁹ Treatment includes intensifying airway clearance and systemic antimicrobial therapy generally directed against the most recent pathogens. Both inpatient and outpatient treatment are used; factors important in this distinction include severity of disease, baseline lung function, microbial organisms and resistance pattern, the presence of additional complications, and the ability to adhere to an outpatient regimen. Acute pulmonary exacerbation is the most common indication for hospitalization in CF and is indicated when episodes are severe, refractory to outpatient management, or not suited to home therapy for psychosocial reasons. Hospitalization facilitates controlled administration of intravenous antibiotics to treat exacerbating infections and provides a setting conducive to sustained intensification of chest physiotherapy. Although the historical standard for pulmonary exacerbations is hospital-based therapy, with adequate resources and adherence, home therapy that includes the use of parenteral antimicrobials and mucus clearance procedures may achieve equivalent outcomes in appropriately selected patients.^{430,431}

In general, the primary goal of therapy is to improve clinical symptoms and return pulmonary function to baseline. However, in some patients, lung function does not return to previous levels despite clinical improvement and can decline further days to weeks following treatment.⁴³³⁻⁴³⁵ A severe decrement in spirometry from baseline is a major risk factor

for sustained loss of lung function, suggesting the need for early and aggressive treatment at the onset of exacerbation.⁴³⁴⁻⁴³⁶

Antibiotic therapy should be broad based due to the polymicrobial nature of CF lung disease and is primarily selected on the basis of respiratory tract culture and susceptibility results. Of note, despite this recommendation, in vitro sensitivities do not predict clinical response, suggesting significant limitations to this general strategy.⁴³⁶ Treatment of *Pseudomonas* is the first consideration, and two mechanistically distinct antibiotics should be used to maximize efficacy, unless oral therapy is used, in which fluoroquinolones are the mainstay, but could potentially lead to increased acquisition of bacterial resistance.⁴³⁷ Aminoglycosides continue to have optimal antimicrobial activity for anti-*Pseudomonas* therapy requiring intravenous antibiotics and have been the mainstay for many years but require monitoring to optimize therapy. Traditional dosing of aminoglycosides two to three times a day has shifted in favor of once-daily dosing.^{438,439} Once-daily dosing, in the range of 8 to 12 mg/kg/day, achieves higher peak concentrations (20 to 30 μ g/mL) that potentiate bactericidal effect and limits toxicity by extending troughs, which are typically undetectable in the setting of normal renal function.^{168,440} Patients should be monitored carefully during aminoglycoside therapy for emergence of nephrotoxicity and ototoxicity. Aminoglycosides are usually paired with a β -lactam to maximize efficacy. A third antibiotic may also be useful to control MRSA or other atypical organism. Although there is no consensus on duration of therapy, a clinical response with respect to symptoms or pulmonary function is usually apparent 4 to 7 days after initiation of therapy. A duration of 10 to 14 days appears to be adequate to achieve maximal improvement in lung function and sustained health in most cases.^{441,442} With refractory infection, treatment for 3 weeks or more is not unusual but may not be successful. Recent studies have demonstrated that FEV₁ plateaus following 10 days of inpatient treatment, raising a question of the benefit and risk of longer hospital and parenteral antibiotic courses.^{431,443} Because there is no clear guideline for duration of therapy, each treatment course requires careful assessment by the clinician. Shorter treatments may improve QOL and compliance, limit drug-associated morbidities, and be less costly. However, this may not be sufficient to clear a chest infection and may result in less sustained benefit and an early recurrence of exacerbation. Prolonged courses of antibiotic therapy should include respiratory tract cultures for bacterial and fungal organisms because antibiotic sensitivities can shift.⁴⁴⁴ For patients requiring frequent courses or long-term home antibiotic therapy, subcutaneous central intravenous catheters can provide stable intravenous access to facilitate treatment. This carries a risk of catheter-associated infections and thrombosis.⁴⁴⁵ For this reason, exogenous estrogen should be avoided in female patients with central venous catheters if possible.

TREATMENT OF LUNG COMPLICATIONS

Treatments directed to control airway infection, limit inflammation, and optimize airway clearance are the cornerstone of therapy in both early and advanced CF lung

disease. Hypoxemic respiratory insufficiency should be recognized and treated with supplemental oxygen. Low-flow oxygen is effective at relieving nocturnal, exertional, and resting hypoxemia and does not usually cause significant hypercapnia.⁴⁴⁶ The development of nocturnal or resting hypoxemia is strongly associated with the onset of pulmonary hypertension and is associated with increased mortality.⁴⁴⁷ Diuretics, inotropic agents, and theophylline provide little to no benefit in CF and are rarely used. Cor pulmonale is an end-stage finding in advanced disease with few viable treatment options beyond those to stabilize lung disease and symptomatically treat pulmonary hypertension.⁴⁴⁸

Acute respiratory failure due to reversible insults can be stabilized by either non invasive or invasive ventilatory support.^{211,449,450} Although the associated mortality with mechanical ventilation is high, it is not absolute. It has been reported that one third of CF patients with advanced lung disease survive events requiring mechanical ventilation.²¹² Mechanical ventilation can also be used as a bridge to lung transplant at appropriate centers.^{212,450,451} Extracorporeal membrane oxygenation has also been used for this purpose.⁴⁵²

Atelectasis is managed by escalating the intensity and frequency of airway clearance and usual therapy directed at pulmonary exacerbations. Systemic or inhaled corticosteroids may be helpful in the presence of asthma, ABPA, or significant airway inflammation refractory to antimicrobial therapy. There is little evidence that bronchoscopy and lavage are effective in treating atelectasis. However, bronchoscopic evaluation of atelectasis and treatment of mucoid impaction in association with endobronchial aspergillosis and ABPA have been described.^{453,454} ABPA typically responds to standard doses of systemic corticosteroids.¹⁹⁰ Inhaled corticosteroids,⁴⁵⁵ suppressive oral antifungal therapy,⁴⁵⁶ and omalizumab⁴⁵⁷ may be useful in limiting the systemic steroid burden.

When small and minimally symptomatic, a pneumothorax can be observed with expectation of spontaneous resolution. Pneumothoraces of greater volume (e.g. >20%) or that compromise ventilation or physiologic stability require chest tube decompression.⁴⁵⁸ Recurrent pneumothoraces are common in advanced lung disease and are associated with higher mortality. Patients with chronic pneumothorax who are clinically unstable or experience significant morbidity may benefit from chemical and/or mechanical pleurodesis.⁴⁵⁹ Prior pleurodesis is not considered a contraindication to lung transplantation.⁴⁵⁹

Major *hemoptysis* is treated with antibiotics and chest rest, although reinstitution of therapy has become more aggressive over time. Supplemental vitamin K should be given if the prothrombin time is prolonged due to malabsorption. Clot stabilization with tranexamic acid and systemic blood pressure reduction with beta-blockade may have some clinical utility.^{195,460} Massive hemoptysis may resolve with conservative therapy, but bronchial artery embolization provides more definitive clinical control and can also be considered in recurrent cases of submassive bleeding.¹⁹⁶

Treatment of Gastrointestinal Complications

Meconium ileus can often be relieved with enemas refluxing water-soluble radiographic contrast into the terminal

ileum under fluoroscopy.¹⁹⁷ If this is not successful, or there is concern for intestinal perforation due to severity of involvement, surgical consultation should be sought. DIOS is typically treated with large volume-balanced electrolyte solutions containing osmotic laxatives (polyethylene glycol) and mucolytics (N-acetylcysteine).⁴⁶¹ Contrast enemas that reach the terminal ileum can complement therapy. In the setting of significant abdominal distension or intractable emesis, concern of bowel obstruction or bilious/fecal emesis necessitates surgical consultation.⁴⁶² *Rectal prolapse* can be voluntarily reduced in patients experienced with techniques involving the abdominal, perineal, and gluteal muscles. Young children often require manual reduction by gentle pressure in the knee-chest position.⁴⁶² Appropriate pancreatic enzyme replacement therapy, improved nutritional status, and control of lung disease usually prevent recurrence. Surgical stabilization of the rectum is required if prolapse is chronic and refractory to medical intervention.

CFTR dysfunction resulting in abnormal bile secretion is believed to be the cause of CF liver disease. *Ursodeoxycholic acid* (URSO) is used to treat primary biliary cirrhosis.²²⁰ Although its impact on the liver disease is unclear, several studies have demonstrated that URSO improves liver function tests; however, the long-term effect on liver function is unknown.⁴⁶³ The thresholds for initiating therapy and clinical outcomes are under investigation; in the absence of empirical data, guidelines presently recommend consideration of URSO treatment.⁴⁶⁴ Aggressive nutritional support should be instituted in the absence of specific therapy. Bleeding esophageal varices that complicate cirrhosis often can be managed with banding or sclerotherapy. Portal hypertension and severe, refractory variceal bleeding have been treated successfully with portosystemic shunting.⁴⁶⁵ Hepatic failure and ascites are treated in standard fashion. Liver transplantation is successful in CF with survival rates at 1 and 5 years reported at greater than 80%.⁴⁶⁶ Pancreatitis is treated with standard measures such as bowel rest and supportive medical care.

Hyperglycemia can complicate CF at any age, but it is generally first encountered in the second and third decades of life.^{467,468} Ketoacidosis is not typically a feature of CF-related diabetes mellitus. Treatment of elevated blood glucose in CF has become more aggressive because advancing survival has provided evidence of the complications of diabetes and increased recognition of its impact on pulmonary disease progression.⁴⁶⁹ Vascular disease affecting the retina and kidneys has been documented in CF patients who have had prolonged hyperglycemia.^{469,470} Thus, long-term control of blood sugar levels is indicated. Intensive screening and management regimens have been recommended.^{468,471-473} Insulin therapy is the mainstay of treatment as its anabolic effects may also be beneficial^{468,472-474}; dietary management is also important.

Surgical Therapy

Endoscopic sinus surgery and nasal polypectomy to relieve obstruction are the most common surgical procedures in CF.⁴⁷⁴⁻⁴⁷⁶ Although most patients experience improvement postoperatively, recurrence is common and often requires repetitive procedures.⁴⁷⁷ The incidence of polyposis tends to wane in adulthood.⁴⁷⁵ More aggressive sinus surgery to

marsupialize the sinus cavity may also be beneficial.⁴⁷⁸ Symptomatic gallstones may require elective cholecystectomy.⁴⁷⁷ Pulmonary resection has historically been considered when severe focal lung disease is thought to lead to clinical instability and accelerated decline in lung function. Although surgical therapy has been reported to stabilize the clinical course and reduce exacerbation frequency, surgical treatment is rare at present likely due to improved treatment strategies and overall health of individuals with CF.^{229,479-482} Patients must be carefully selected because short-term loss of lung function postoperatively is expected.⁴⁸³ Massive hemoptysis refractory to standard therapy may require lobectomy.

Nutrition

Improved nutritional status in patients with CF is associated with better long-term clinical outcomes.⁴⁸¹ Patients with CF have increased caloric requirements that have been attributed to residual malabsorption, increased work of breathing, and factors related to infection and inflammation. Dietary recommendations include a high calorie (20% to 50% greater than standard recommended intake), high-protein diet including a moderate amount of dietary fat (35% to 45% of caloric intake), and limited processed carbohydrates.⁴⁸⁴ Patients with a body mass index below the 25th percentile are typically considered to be in nutritional failure and warrant aggressive nutritional counseling and dietary supplementation. If nutritional counseling is unsuccessful, consideration of appetite stimulants, or alternatively gastrostomy tube feedings, is warranted because supplementation with elemental dietary preparations by mouth is unlikely to be sustained over an extended period of time.

Due to pancreatic insufficiency, 90% of patients with CF require pancreatic enzyme replacement therapy. The enzymes are supplied as capsules containing acid-resistant enteric coated granules, containing doses of lipase from 3,000 to 40,000 units. Dosing is typically based on weight and is adjusted on the basis of the presence of symptoms of malabsorption such as abdominal cramping, excessive flatulence, and fatty stools. Dosage ranges should be limited to current guidelines (2500 lipase units/kg/meal; 10,000 lipase units/kg/day). Dosages exceeding these limitations have been associated with fibrosing colonopathy.⁴⁸⁵⁻⁴⁸⁸

A daily multivitamin is standard to CF care with additional supplementation depending on serum levels or clinical factors. Vitamins A and E are often adequately supplied by a standard daily multiple-vitamin preparation. Vitamin A deficiency is easily corrected by dietary supplementation. Symptomatic deficiency is rare and typically is found in patients who do not take supplementary vitamins or pancreatic enzymes but may result in increased intracranial pressure, xerophthalmia, and night blindness. Vitamin D deficiency presenting as rickets is rarely seen. Patients with CF often have inadequate levels (<30 to 60 ng/mL) that can be refractory to high-dose supplementation. Bone demineralization is common, and the considerable interest regarding the association of inadequate vitamin D levels with poor health-related outcomes has led to recommendations of aggressive supplementation. Vitamin E is deficient only in unsupplemented patients and rarely causes increased red

blood cell destruction and neuroaxonal dystrophy.⁴⁸⁹ Vitamin K deficiency may result in bleeding diathesis. Although clinically significant hemorrhagic problems manifest mostly in children, vitamin K deficiency in the setting of hemoptysis may present significant complications in older patients. Other vitamins and trace minerals, specifically zinc, may be deficient and require supplementation on a selective basis.⁴⁹⁰

Psychosocial Factors

Outcomes are improving and new therapies hold even greater promise, but CF remains a fatal chronic disease. With the advent of newborn screening and patients surviving into adulthood, the psychosocial aspects of CF have broadened and continue to affect the patient, family, and community. Medical therapies continue to offer significant benefit but can be limited by the patient's psychosocial well-being, attitude, and ultimately adherence to therapy. Approaches to delivery of clinical care that promote a positive self-concept and support the patient and/or family to manage their medical therapy and maximize health-related QOL are likely to have a positive impact on outcomes and ultimately on longevity. Providers with expertise in psychosocial support are invaluable to the CF care team.⁴⁸⁵ Major depression is a common comorbidity as patients grow older and can be a negative influence on clinical outcome; aggressive monitoring and treatment are warranted.⁴⁹¹

Lung Transplantation

Sequential double-lung transplantation is an accepted therapy for respiratory failure secondary to CF.⁴⁹² Living lobar transplantation is an effective alternative to conventional cadaveric lung transplants but is only performed in selected centers.⁴⁹³ More than 2300 lung transplants have been performed for CF around the world, and the rate is increasing. The 5-year survival is just above 50%, which compares favorably to the survival of lung transplant performed in other lung diseases.⁴⁹⁴ Given the limited survival and complex treatment required, consideration of lung transplantation requires a careful psychological and social evaluation. Should lung transplantation be chosen, patients should be thoroughly evaluated and referred when they have a survival benefit or predicted mortality in the range of 2 to 3 years; prediction formulas can assist with this process.¹⁷⁴ Following successful transplantation, the patient can experience a dramatically improved respiratory status and QOL, but significant medical treatment burden can remain.

Key Points

- Cystic fibrosis (CF) is the most common monogenetic disease in Caucasians and results from mutations in the *CF transmembrane conductance regulator* (CFTR) gene.
- Absent CFTR causes delayed mucociliary clearance, abnormalities in mucus, and a host defense defect, initiating chronic, progressive sinopulmonary infections and a cycle of lung destruction, leading to bronchiectasis and end-organ failure.

- Extrapulmonary manifestations are observed where CFTR is highly expressed normally, such as in the endocrine and exocrine pancreas, gastrointestinal tract, skin, bone, and male reproductive tract.
- The diagnostic paradigms emphasize early detection by newborn screening and a high index of suspicion to recognize atypical cases later in life, which are generally caused by *CFTR* alleles that code for partially functional CFTR.
- Effective treatment and monitoring through a network of specialized CF care and research centers have improved morbidity and mortality.
- Aggressive treatment of CF pulmonary exacerbations is required to delay progression and reduce complications of end-stage lung disease.
- Treatment strategies for chronic lung disease generally address downstream manifestations of CF pathophysiology; such treatments include rehydrators of diminished airway surface liquid, mucolytics to enhance mucus clearance, antimicrobial therapies, and chronic anti-inflammatory agents.
- Recently, the successful development and approval of ivacaftor for CF patients with the G551D *CFTR* mutation has provided a roadmap that has invigorated investigators working to develop novel modulators of CFTR function to correct the underlying defect caused by the most common *CFTR* alleles.

eFIGURE IMAGE GALLERY

eFigure 47-1 Cystic fibrosis (CF): chest radiographic and chest CT findings. **A**, Frontal chest radiograph in a 4-year-old patient with CF shows mildly increased lung volumes associated with central airway thickening and extensive linear opacity representing bronchiectasis and bronchial wall thickening. **B–E**, Axial chest CT displayed in lung windows shows extensive cylindrical bronchiectasis (*arrows*), as well as extensive bronchial wall thickening and small nodules (*arrowheads*), the latter reflecting distal bronchial and small airway impaction. (Courtesy Michael Gotway, MD.)

eFigure 47-2 CF: chest radiographic and chest CT findings. **A**, Frontal chest radiography in a young adult with CF shows large lung volumes associated with central airway thickening and extensive linear opacity representing bronchiectasis and bronchial wall thickening. **B–E**, Axial chest CT displayed in lung windows shows extensive cylindrical bronchiectasis (*arrows*), as well as extensive bronchial wall thickening and small nodules (*arrowhead*), the latter reflecting distal bronchial and small airway impaction. (Courtesy Michael Gotway, MD.)

eFigure 47-3 CF: predominant right upper lobe involvement. A and B, Frontal chest radiograph in two separate patients with CF shows multifocal bronchial wall thickening and dilation, most pronounced in the right upper lobe. (Courtesy Michael Gotway, MD.)

eFigure 47-4 CF with hemoptysis treated with bronchial arterial embolization. **A**, Frontal chest radiograph shows central perihilar predominant bronchial wall thickening and bronchiectasis. Focal consolidation (arrow) in the right lower lobe was new compared with prior studies. **B–E**, Axial enhanced chest CT displayed in lung (**B** and **C**) and soft tissue (**D** and **E**) windows shows multifocal bronchiectasis (arrow), typical of CF. Bronchial artery hypertrophy (arrowhead, **D**) is present, commonly observed in patients with chronic inflammatory airway diseases. **E**, A mildly hyperattenuating mass (double arrowheads) is present in the anterior right lower lobe, correlating with the new finding at chest radiography and presumed to reflect hematoma in the setting of a patient with CF and new hemoptysis. **F** and **G**, Pre (**F**) and post (**G**) catheter bronchial artery embolization images show an enlarged bronchial artery (arrowhead) associated with a prominent “vascular blush” (double arrowhead) in the region of the anterior right lower lobe mass at chest CT. The postembolization image (**G**) shows lack of opacification of the region of the vascular blush, and essentially no flow is now seen in the hypertrophied bronchial artery (arrowhead). (Courtesy Michael Gotway, MD.)

eFigure 47-5 CF with spontaneous pneumothorax. Frontal chest radiography shows typical changes of CF, included extensive bronchiectasis, and peribronchial consolidation with large lung volumes. A small, spontaneous right apical pneumothorax (arrowheads) is present. (Courtesy Michael Gotway, MD.)

eFigure 47-6 CF: mosaic perfusion. A–D, Axial chest CT through the lung bases displayed in lung windows shows cylindrical bronchiectasis (*arrowheads*) and extensive bronchial wall thickening, typical of CF. Extensive, bilateral inhomogeneous lung opacity is present, manifesting as geographic areas of increased and decreased pulmonary parenchymal attenuation. The areas of decreased attenuation (see *black outlines* in **A** and **D**) show small pulmonary vessels, reflecting vasoconstriction and decreased pulmonary parenchymal perfusion due to air trapping, and are referred to as “mosaic perfusion.” Although the areas of increased attenuation resemble ground-glass opacity, they actually represent relatively normal but hyperperfused pulmonary parenchyma. Such findings may happen with large or small airway obstructive disorders. (Courtesy Michael Gotway, MD.)

eFigure 47-7 CF: chest radiographic and chest CT findings of small airway impaction/obstruction. A, Frontal chest radiography in a patient with CF shows large lung volumes associated with central airway thickening and extensive linear opacity, representing bronchiectasis and bronchial wall thickening. A number of small, poorly defined upper lobe opacities, particularly on the right, are evident. **B–D,** Axial chest CT displayed in lung windows shows extensive cylindrical bronchiectasis (*arrows*) and extensive bronchial wall thickening. Numerous small, solid, centrilobular nodules showing branching configurations, consistent with “tree-in-bud” opacity (*arrowheads*), are evident. (Courtesy Michael Gotway, MD.)

eFigure 47-8 Upper respiratory tract manifestations of CF: sinusitis. A and B, Axial sinus CT shows complete opacification of the maxillary sinuses (M) and ethmoid (E) air cells. (Courtesy Michael Gotway, MD.)

eFigure 47-9 Gastrointestinal complications of CF: meconium ileus with small bowel obstruction. Frontal view of the abdomen shows dilated small bowel with numerous gas-fluid levels (arrows) representing small bowel obstruction. The appearance is not specific for meconium ileus, but that diagnosis was proved subsequently. (Courtesy Michael Gotway, MD.)

eFigure 47-10 Gastrointestinal complications of CF: meconium ileus. Postevacuation image following contrast enema shows a small, opacified colon, consistent with a “microcolon.” Distended small bowel (arrowheads), consistent with small bowel obstruction, is present. (Courtesy Michael Gotway, MD.)

eFigure 47-11 Gastrointestinal complications of CF: distal intestinal obstruction syndrome. A, Axial and B, coronal contrast-enhanced abdominal-pelvic CT in a child with CF shows opacified normal caliber proximal small bowel but dilated, debris-filled distal small bowel (*), consistent with the distal intestinal obstruction syndrome. C, left colon. (Courtesy Michael Gotway, MD.)

eFigure 47-12 Gastrointestinal manifestations of CF: enlarged appendix. A, Coronal and B and C, axial enhanced abdominal CT shows a dilated appendix (arrows); this finding was unchanged from a study several years earlier. The colon (arrowheads) is somewhat redundant and thick-walled, with mild infiltration of the pericolonic fat; these findings may be occasionally encountered in CF patients as well. (Courtesy Michael Gotway, MD.)

Figure 47-13 Gastrointestinal manifestations of CF: fatty replacement of the pancreas. **A–F,** Axial enhanced abdominal CT in a patient without CF shows a normal pancreas (*white outline shape*); note close relationship of the tail of the pancreas to the spleen (S). The normal pancreas is obliquely oriented with the tail superiorly and left laterally positioned compared with the more medial and inferiorly located pancreas head (*outline shape* in panels **E** and **F**); the head of the pancreas is closely related to the junction of the second and third portions of the duodenum (*arrowheads* in **F** and **L**. The enteric tube in **L** also marks the position of the duodenum). **G–L,** Axial unenhanced abdominal CT in a patient with CF shows complete fatty replacement of the pancreas—note the homogeneous low attenuation, consistent with fat and equivalent in attenuation to subcutaneous fat, occupying the position of the pancreas (*white outline shape* in **G–L**). Ao and arrow, abdominal aorta; Liv, liver; R, renal/kidney. (Courtesy Michael Gotway, MD.)

INTRODUCTION

Bronchiectasis is defined by dilation, or ectasia, of the airways or bronchus. The primary clinical manifestations of bronchiectasis are recurrent, chronic, or refractory infections. Other significant sequelae include hemoptysis, chronic airflow obstruction, and progressive impairment of breathing. In the preantibiotic era, secondary amyloidosis and embolic brain abscesses were reported as consequences of chronic suppuration in the lungs; such complications are extremely rare now in industrialized nations.

There are many and varied pathways that lead to the development of bronchiectasis (Table 48-1). Broadly, bronchiectasis may develop because of an incidental event or episode that does not reflect the patient's intrinsic host defenses. Examples might include a necrotizing pneumonia following aspiration or chronic infection distal to an obstructing bronchial adenoma. Often, however, bronchiectasis evolves due to conditions that are inherent in the patient's basic genetic constitution. The most common and dramatic example of this is *cystic fibrosis* (CF). The distinction between these two models is an important element of prognosis and management.

A central issue in understanding the pathogenesis of bronchiectasis is whether infection is truly the proximate cause of bronchiectasis or whether infections develop because of an underlying predisposing condition. For example, it has been a commonly held adage that many cases of bronchiectasis in adults are due to childhood bouts of pertussis or measles.¹ Pasteur and coworkers investigated the causative factors in 150 adults with bronchiectasis.¹ In 70 (47%) of the patients, they were able to identify one or more “causes” for the bronchiectasis. Although they found that “childhood pneumonia, pertussis, or measles” was a cause or contributed to the cause of bronchiectasis in 44 of the 70 patients, it is important to emphasize that this finding was based on recall of remote past medical history and provides at most only an associative link and not a causal link.¹ Although these childhood infections can

undoubtedly cause bronchiectasis, one might be skeptical of this simple construct, asking why formerly common childhood illnesses resulted in bronchiectasis in only a small proportion of the patients. The question that should be addressed more thoroughly is whether the individuals were particularly vulnerable to complications; for example, did the pertussis or measles result in excessive damage due to innate susceptibility of the hosts?

CLASSIFICATION

Although there is considerable overlap and coexistence among the various forms of bronchiectasis, the radiographic patterns and distribution may provide clues to diagnosis, management, and prognosis.² Thus, characterizing the morphologic features and distribution of bronchiectasis is a useful exercise. In this era, bronchiectasis is primarily identified and described by chest *computed tomography* (CT), especially *high-resolution CT* (HRCT; see later).

Cylindrical bronchiectasis is described as failure of the involved airways to taper progressively in their distal course. Usually, in this condition the bronchial walls are smooth or regular (Fig. 48-1A). *Varicoid* bronchiectasis is an allusion to varicose veins and is marked by irregular dilation, narrowing, and outpouching of the airways (see Fig. 48-1B). *Saccular* bronchiectasis, also known as cystic bronchiectasis, includes focal or cystic distortion of the distal airways; it may be isolated (see Fig. 48-1C) or may be more confluent, producing the appearance of bronchiectatic consolidation and volume loss (Fig. 48-2).

A traditional clinical distinction within bronchiectasis has been “wet” versus “dry.” Historically it was observed that some patients with bronchiectasis had continuous or frequent productive cough that typically yielded copious, often purulent secretions—hence “wet.” Others who carried the diagnosis of bronchiectasis rarely experienced cough, and if they did so, rarely was their cough productive—hence “dry.” Independent of cause, “wet” and “dry”

Figure 48-2 Bronchiectatic consolidation. The inferomedial aspect of the right middle lobe is involved with a coarse cystic process, with essentially no normal remaining lung. Similar changes are often seen in the inferior segment of the lingula. In many cases such findings are associated with nontuberculous mycobacterial infection; however, in this case the patient was infected only with gram-negative bacilli, including *Pseudomonas aeruginosa* and *Alcaligenes xylosoxidans*.

bronchiectasis tend to have distinct localization patterns. Bronchiectasis involving dependent zones (lower lobes, the right middle lobe, or the lingular segment of the left upper lobe) tends to entail frequent or chronic infections and to be “wet” in nature. By contrast, chronic bronchiectasis isolated to the upper lobes is less commonly involved with infection and is often “dry.” Presumably, this is related in large measure to gravity-driven drainage of the upper zones in contrast to pooling of secretions in the dependent regions.

EPIDEMIOLOGY

There are no systematic data on the incidence or prevalence of bronchiectasis. Historically it has been thought that, as

antibiotics and vaccines were introduced in the 20th century, there has been a declining rate of bronchiectasis.^{3,4} The presumed mechanism was that these modalities lessened the frequency, severity, and duration of lower respiratory tract infections that might result in bronchiectasis. In this regard it is suggested that bronchiectasis remains relatively more common in regions where prompt and effective medical care is not available.⁵ In the United States it is estimated that the prevalence of bronchiectasis is approximately 4 per 100,000 for young adults and 272 per 100,000 among those 75 years old or older.⁶ In a retrospective analysis of hospital discharges from 12 states with bronchiectasis as a discharge diagnosis recorded in the state inpatient databases, the average annual bronchiectasis-associated hospitalization rate from 1993 to 2006 was 16.5 per 100,000.⁷ Furthermore, during this time period the age-adjusted rate increased significantly with an average annual percentage increase of 2.4% for men and 3.0% for women.⁷ Whether these rising rates reflect a true rise in incidence or enhanced detection of “incidental bronchiectasis” due to more frequent use of CT scans is not known. The observation that bronchiectasis was the *primary* diagnosis in a minority (<20%) of all the bronchiectasis-associated hospitalizations supports the concept that greater incidental diagnosis is being made from more frequent use of CT scans.⁷

In the United States there appear to be increasing numbers of bronchiectasis cases associated with environmental or *nontuberculous mycobacteria* (NTM).^{8,9} Recent studies estimate the incidence of NTM lung disease in the United States to be 5 to 6 cases per 100,000 and as high as 15.5 cases per 100,000 in persons over 50 years old.¹⁰⁻¹³ Furthermore, due to high rates of treatment failure or relapses, the prevalence of NTM lung disease is estimated to be 10 to 40 cases per 100,000.¹⁴ Based on serial observations in a cohort now numbering approximately 2000, our group believes that, in the majority of cases, the mycobacterial infections both initiate and “drive” the evolution of bronchiectasis. Of interest, this disorder seems disproportionately to involve females, predominantly slender white women.^{15,16} Although it is not possible to determine whether the incidence of NTM-associated bronchiectasis is truly increasing, or is an artifact of increased awareness and improved diagnostic techniques, or both, there is reason to suspect that the exposure and infection from NTM is increasing. For example, there has been an increase in the positive skin test reaction to Battey antigen (purified protein derivative-B of *Mycobacterium intracellulare*) from 11% in the 1971–1972 period to 17% positivity in the 1999–2000 period.¹⁷

PATHOGENESIS

Various mechanisms operate to produce permanent, pathologic dilation and damage of the airways. In simplest terms, they may be thought of in terms of traction, pulsion, and weakened tensile strength of the airways. In most cases the pathogenesis becomes inextricably linked with and propelled by the destructive effects of chronic infection.

In normal lungs, airways are held patent by a combination of negative intrapleural pressure (which maintains the

lungs in an inflated state) and the cartilaginous rings of the trachea and the large and medium airways. The distending forces of the negative intrapleural pressure are transmitted to the airways by a diffuse system of interstitial tethering. As the lung undergoes fibrotic changes consequent to disorders such as sarcoidosis, interstitial lung disorders, or infections such as tuberculosis, local retractile forces result in fixed dilation of the airways, or “traction” bronchiectasis.

The prototypic “pulsion” bronchiectasis (i.e., permanent airway dilatation as a result of intense inflammation originating in the lumen) is seen with *allergic bronchopulmonary aspergillosis* (ABPA). In ABPA there are intense, immunologically mediated reactions to inhaled *Aspergillus* that has lodged in the airways. The proliferating fungi form large mucoid conglomerates that fill the central airways; a sequela of this airway inflammatory process and mucoid impaction is bronchiectasis (Fig. 48-3).

Weakness of the airways contributing to the development of bronchiectasis may take many forms. Classic postinfectious bronchiectasis presumably is mediated in part by chronic damage to the walls of the airways, resulting in secondary loss of structural integrity.^{18,19} This is coupled with scarring and loss of volume of the local lung units, leading to regional increases in retractile forces. Examples of primary weakness of the airways contributing to bronchiectasis include Mounier-Kuhn syndrome (congenital tracheobronchomegaly due to atrophy of airway elastic fibers), Williams-Campbell syndrome (absence of cartilaginous rings in the segmental and subsegmental generations of bronchi), Marfan syndrome, and relapsing polychondritis. A case is made later that the apparent propensity of slender women for bronchiectasis may be based in part on mechanisms analogous to Marfan syndrome.

One particular component of the posited role of “weakened airways” in the pathogenesis of bronchiectasis that has not received adequate attention is the potential impact of airway collapsibility on the effectiveness of the cough mechanism. Coughing is an essential, primary element of lung defense. An effective cough sends columns of air rushing upward through the bronchial tree at peak speeds measured in the range of 600 mph.²⁰ To generate these high flow rates, the cartilaginous rings must have the structural integrity to remain patent while the posterior membranous element invaginates into the lumen of the airway, thereby decreasing the cross-sectional diameter of the airway and accelerating airflow. While performing bronchoscopy on patients with bronchiectasis, it is common to observe extraordinary collapsibility of the airways, virtually obstructing the bronchi. It seems likely that such amplified airway compressibility impedes the air-driven propulsion of secretions out of the bronchial tree and helps propagate the chronic or recurring infections that mark most cases of bronchiectasis.

“VICIOUS CIRCLE” AND MICROBIOLOGY

Because the lung is constantly exposed to the environment, resident or recruited lung phagocytes such as macrophages,

Figure 48-3 Allergic bronchopulmonary aspergillosis with bronchiectasis and bronchial mucus impaction. **A and B,** Axial chest CT displayed in lung windows shows multifocal, bilateral tubular opacities (arrowheads) consistent with mucus impaction. **C–F,** Axial chest CT from another patient displayed in lung (**C and E**) and soft tissue (**D and F**) windows shows tubular branching opacities (arrows) in the left lower lobe consistent with mucus impaction. Note that the opacities show faintly increased attenuation on the soft tissue windows (arrows in **D and F**), representing mucus impaction containing calcium salts and/or metallic ions. (Courtesy Michael Gotway, MD.)

dendritic cells, and neutrophils play an important host-defense role against inhaled or aspirated microbes. In addition, the host employs an array of other mechanisms to defend against microbial organisms that invade the respiratory tract, including the cough reflex, mucociliary escalator, antimicrobial peptides (lysozymes, secretory leukocyte protease inhibitor, defensins, and cathelicidin), secretory immunoglobulin (Ig) A, and with more sustained infection, the recruitment of T effector lymphocytes. Airway epithelial cells are also able to contribute to the lines of defense by secreting antimicrobial peptides and phagocytosing microbes.^{21,21a} Thus, in addition to the three aforementioned mechanisms by which physical forces or primary weakness of the airway walls may result in bronchiectasis, the other major element in the pathogenesis of bronchiectasis is the vicious circle of recurrent or sustained infection and inflammation, as described by Cole.^{22,23} Transmural inflammation causes damage to the bronchi and bronchioles, which then become susceptible to chronic colonization by certain microorganisms such as *Pseudomonas aeruginosa*, NTM, and *Aspergillus*, resulting in further injury and lessened capacity to resist infection. Analysis of cellular and noncellular constituents in the bronchiectatic airways typi-

cally demonstrates intense infiltration by neutrophils as well as mononuclear cells and lymphocytes.²⁴ Indeed, bacterial load in the airways correlates directly with markers of airway inflammation in the sputum (e.g., myeloperoxidase activity, neutrophil elastase activity, interleukin-8 [IL-8], tumor necrosis factor- α [TNF- α], and IL-1- β) and with markers of systemic inflammation in the serum (e.g., intercellular adhesion molecule-1, E-selectin, and vascular cell adhesion molecule-1).²⁵

Another important component in the development of bronchiectasis is impaired mucociliary clearance, a key factor in the pathophysiology of CF and *primary ciliary dyskinesia* (PCD)—discussed in more detail later—diseases almost always characterized by bronchiectasis. In CF and PCD, production of abnormal mucus and dysfunctional cilia, respectively, prevent sufficient clearance of microbes, thus increasing the risk for colonization.²⁶ When these initial defenses are unable to contain the infection, a robust immune response ensues, orchestrated by airway epithelial cells and phagocytes through the release of inflammatory cytokines and chemokines that include macrophage inflammatory protein-2, IL-8, and TNF- α . Consequently, airway infiltration by predominantly neutrophils, macrophages,

Figure 48-4 The prominent role of neutrophils and neutrophil elastase in the pathogenesis of bronchiectasis. Diagram shows a dilated cystic bronchus lined by epithelial cells. Regardless of the primary underlying cause of bronchiectasis, the “vicious circle” phase of bronchiectasis is dominated by the influx of neutrophils (polymorphonuclear leukocytes [PMNs], green cells). PMNs are attracted by the release of chemokines such as interleukin-8 (IL-8) and leukotriene B_4 (LTB_4) from macrophages, and IL-17 from T_H17 cells; their migration from the bloodstream into the airways is facilitated by increased expression of the E-selectin and intercellular adhesion molecule-1 on endothelial cells, which bind to L-selectin and CD11 on PMNs, respectively. PMNs, which then enter the airway lumina through gaps between epithelial cells, have a relatively short life span, undergoing both apoptotic and necrotic cell death. PMN proteases such as elastase but also cathepsins, matrix metalloproteinases, and proteinase-3 can cause epithelial cell damage and induce further inflammation. In addition to the tissue damage, elastase can induce mucous hypersecretion, inhibit ciliary function, and impair efferocytosis (i.e., phagocytosis of apoptotic neutrophils) by cleavage of phosphatidylserine (PS) on the surface of apoptotic cells, preventing binding to PS receptors (PSRs) on macrophage surfaces. Elastase also inhibits killing of bacteria by inhibiting the opsonization of bacteria through degradation of opsonins immunoglobulin G (IgG) and complement component $iC3b$ as well as cleavage of $Fc\gamma$ receptors ($Fc\gamma R$ s) and complement receptor (CR) 1. Black arrows, activation or “leading to”; red “T-bars,” inhibition or degradation.

and lymphocytes causes damage to the airway epithelium through the release of various proteolytic enzymes such as neutrophil elastase and metalloproteinases, which results in erosion of mucosal barriers, creating microabscesses that can harbor bacteria. Neutrophil elastase has also been shown to cause ciliary dysfunction, mucous gland hyperplasia, and increased mucus secretion, thus further impairing clearance (Fig. 48-4).²⁷⁻²⁹ Moreover, elastase and other proteases released by neutrophils can cleave $Fc\gamma$ receptors and complement receptor 1 from neutrophil surfaces as well as digest immunoglobulins and complement components from bacterial surfaces. These activities impair opsonization of bacteria and reduce recognition of bacteria by neutrophils, leading to decreased phagocytosis and bacterial killing (see Fig. 48-4).^{30,31} Neutrophils undergo both necrotic and apoptotic forms of cell death. Necrotic neutrophils can incite more inflammation as well as the release of highly viscous DNA, which contributes to the volume and inspissated quality of bronchiectatic mucus. Although phagocytosis of apoptotic neutrophils—a process known

as efferocytosis and requiring engagement of phosphatidylserine on apoptotic cells and phosphatidylserine receptor on macrophages—can limit inflammation, elastase can inhibit efferocytosis by cleavage of phosphatidylserine.³² In summary, damaged airways are vulnerable to infection, leading to more damage.

Simple colonization and infection of the airways is not sufficient to produce true bronchiectasis. Sputum from patients with smoking-related chronic bronchitis typically yields organisms such as *Haemophilus influenzae*, *Haemophilus parainfluenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis*, a microbial spectrum similar to that seen with bronchiectasis.³³⁻³⁶ In addition, in this setting there is heavy cellular traffic and the presence of a variety of inflammatory mediators. However, significant bronchiectasis is uncommon among patients with typical chronic bronchitis. Hence it is probable that systemic conditions or focal disturbances as described earlier are required for the development of classic bronchiectasis. Notably, however, the appearance in respiratory secretions of *P. aeruginosa* on a

chronic or recurring basis does pose the risk for deleterious effects on ciliary function and other host defenses.³⁷ Pseudomonal infections may be of particular importance due to their role in the formation of biofilms (see later). Three reports note worsened lung function^{37,38} and quality of life³⁹ among bronchiectasis patients who become infected with *P. aeruginosa*. In a longitudinal study of the microbiologic characteristics of 89 patients with bronchiectasis over a 5-year period, 47% were colonized with *H. influenzae*, 12% with *P. aeruginosa*, and 21% had no identifiable pathogen. After 5 years there was a slight increase in the number of those colonized with *P. aeruginosa*. As expected, those with the mildest disease had no identifiable pathogens, whereas those with the worst disease were colonized with *P. aeruginosa*.⁴⁰

As previously noted, NTM can colonize bronchiectatic airways as well as cause bronchiectasis. Based on two recent studies from the United Kingdom, the prevalence of NTM isolated from a heterogeneous group of bronchiectatic patients was approximately 2% to 10%.⁴¹ Furthermore, bronchiectatic patients with NTM infections also have a greater likelihood of having concomitant *Aspergillus* lung disease.⁴²

Genetic techniques have been used to identify the bacterial flora in patients with bronchiectasis. Using 16S ribosomal RNA gene pyrosequencing of paired induced sputum and bronchoalveolar lavage samples, the bacterial flora of lower airway samples was analyzed in 41 adult patients with non-CF bronchiectasis.⁴³ A group of core bacterial species, defined as those frequently detected, was found to consist of commonly recognized pathogens (e.g., *P. aeruginosa*, *H. influenzae*, and *S. pneumoniae*) but also organisms not typically detected by routine cultures (e.g., *Veillonella*, *Prevotella*).⁴³ This burgeoning field of genetically categorizing lung microbiota in patients with bronchiectasis and determining the significance of the microbiota signature with relevant clinical end points such as exacerbations is still in its infancy. Although a study showed that there was no significant difference in the overall microbial community diversity between patients with stable bronchiectasis and those with exacerbations, it was clear that *Acinetobacter* and *Stenotrophomonas* were seen primarily during exacerbations.⁴⁴ In an editorial that accompanied this report, the authors raised the critical question of whether analyzing the mountain of 16S-derived microbiota data in the context of the microbial community (“the forest”) masks the importance of individual microbes detected (“the trees”).⁴⁵

BIOFILMS

Costerton⁴⁶ in 1984 hypothesized that *P. aeruginosa* in human infections “attaches to solid or tissue surfaces and grows predominantly in biofilms that release mobile swarmer cells into the surrounding fluid phase.” These natural and pathogenic biofilms are covered by an exopolysaccharide matrix (glycocalyx) that serves as a barrier against hostile environmental factors such as host defense mechanisms and antibiotics.⁴⁶ Since this discovery, there has been clear evidence for the clinical significance of biofilms in promoting chronic infection in the airways of CF patients⁴⁷ as well as a variety of other infections.⁴⁸ *P.*

aeruginosa, among its various attributes, enjoys cilia-driven motility, which appears critical in the aggregation phase of early biofilm formation.⁴⁹ Once biofilm formation commences, features of growth and gene activation that release virulence factors are influenced by a type of cell-cell communication called “quorum sensing.” Owing to a combination of physicochemical factors that protect the microbes from host defense cells and/or antibiotics, infection may persist despite aggressive treatment. In vitro testing indicates that bacteria embedded in biofilms can survive despite exposure to concentrations of antimicrobials that exceed the minimal inhibitory concentration by 1000-fold.⁵⁰ We may anticipate that future understanding and optimal management of patients with chronic bronchiectasis will entail interventions to modify or interfere with biofilms.⁴⁹

ASSOCIATED DISORDERS AND PREDISPOSITIONS

LUNG INJURY DUE TO ACUTE INFECTION

In the traditional model of lung injury due to acute infection, patients are deemed to have normal airways and lungs until they experience a specific lower respiratory tract infection resulting in irreversible damage to their airways. In the modern era in industrialized nations, most episodes of lower respiratory tract infection—adequately treated—resolve without residual damage. However, among the older generations who were not protected by readily available antibiotics and vaccines, there are individuals who offer a convincing story of recurring, localized infections following a discrete episode of “pneumonia” in their childhood or early adult years that presumably produced irreversible damage leading to bronchiectasis.¹

Specific traditional pathogens to which bronchiectasis has been ascribed include *Bordetella pertussis*, mucoid strains of *S. pneumoniae*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, adenoviruses, rubeola (measles), and influenza. Chronic granulomatous pathogens commonly related to bronchiectasis include *Mycobacterium tuberculosis*, *Histoplasma capsulatum*, and NTM such as *Mycobacterium avium* complex (MAC). In addition, mixed infection, including anaerobic mouth flora related to aspiration, may result in extensive damage to the parenchyma (“lung abscesses”) with subsequent bronchiectasis.

CYSTIC FIBROSIS

CF and CF variants are arguably the most common causes of bronchiectasis in the United States and other industrialized nations of the Western Hemisphere today. Being the most common autosomal recessive disorder among whites (1 in 2000 to 2500 live births),⁵¹ CF is increasingly prevalent as improved therapies allow those who are afflicted to live longer. At present, there are approximately 30,000 CF patients in the United States with approximately 45% of them estimated to be over 18 years old, or roughly 12,000 to 14,000 adults with CF. In the next decade it is predicted that about 50% of all CF patients

will be adults.⁵² The specific manifestations, severity, and rapidity of progression of CF vary highly according to the genotype and other modifying factors. However, the majority of those with childhood-onset CF who survive into their adolescence or early adult years have bronchiectasis (eFig. 48-1). (See Chapter 47 for details.)

In addition to these “typical” cases in which CF is recognized early in life, variants may be present in the population that predispose to bronchiectasis in adults. Among a large series of adult patients seen at *National Jewish Health* (NJH) in Denver with bronchiectasis associated with NTM, 117 of 865 (13.5%) were found to have one or more abnormal alleles of the cystic fibrosis transmembrane regulator gene, *CFTR*,⁵³ well in excess of the anticipated carrier rate of 6% in the general population. In 19 of these patients (2.2% overall), there were two abnormal alleles and, in the remaining 98 (11.3%), there was only one mutation. Of note, the mean age of these patients was 61 years. The clinical importance of these heterozygous mutations may be disputed; however, patients in this cohort had a high frequency of chronic airflow obstruction, sinusitis, difficulties with conception, and coinfection with pathogens typical of CF, including mucoid strains of *P. aeruginosa*—all features compatible with clinical CF. Among another series of patients with bronchiectasis and/or NTM lung disease, 24 of 50 (48%) had one or more *CFTR* mutations.⁵⁴ Similarly, among a cohort of 63 patients with NTM lung disease studied at the National Institutes of Health, 36% had mutations in the *CFTR* gene.⁵⁵ Consistent with the assertion that these heterozygous mutations are clinically relevant is a series of 30 patients with clinical features of CF who were reported to have normal *CFTR* alleles on comprehensive gene sequencing.⁵⁶ The authors concluded that factors other than mutations in *CFTR* could result in a clinical condition consistent with CF. It is our contention that heterozygous anomalies in the CF gene act as a predisposing factor for bronchiectasis.

Based on contemporary understanding of the complex and diverse features of CF, there appear to be two groups in whom bronchiectasis develops. The first and obvious group includes those with classic infancy/childhood-onset disease in whom clinical and laboratory data readily confirm the diagnosis of CF. The other group involves those with less severe disease that manifests later in life and for whom diagnostic testing is ambiguous.⁵⁷ Sweat chloride test results may or may not be abnormal, and genotyping may demonstrate heterozygous or even normal *CFTR* alleles. We might include under this rubric males with congenital bilateral absence of the vas deferens,⁵⁸ who have not been consistently regarded as having variant CF. In addition, there are a wide variety of genetic factors other than *CFTR* that influence the clinical phenotypes of the patients.⁵⁹ (See Chapter 47 for additional discussion.)

Bronchiectasis has been described in a condition identified in the 1970s called Young syndrome. Although Young syndrome is not CF, it has a number of similar clinical features such as bronchiectasis, sinusitis, and infertility.⁶⁰ However, unlike CF, the genetic basis for Young syndrome is not known, and, because the definition includes azoospermia, it is seen only in males. Furthermore, whereas the azoospermia related to CF is due to congenital absence of the vas deferens, in Young syndrome it is due to obstruction

in the distal epididymis (i.e., obstructive azoospermia).^{58,61} In a comprehensive study of 15 patients with a clinical diagnosis of Young syndrome, the mean nasal mucociliary clearance, as measured by the saccharin test, was prolonged nearly threefold compared to nonsmoking controls, but the ciliary beat frequency and ultrastructural anatomy of the cilia were considered to be within normal limits.⁶¹ Interestingly, in one subject in whom a sample of epididymis was available, microtubular disarrangement—mostly missing or “displaced” microtubules—was seen in approximately 13% of the cilia examined.⁶¹ Because the incidence of Young syndrome appears to be decreasing dramatically since it was originally reported in the 1970s, it has been hypothesized that Young syndrome may be due to poisoning from mercurous chloride (calomel), a compound contained in teething powder and antihelmintics that has since been banned.^{62,63} Furthermore, we posit that, with more comprehensive testing for the *CFTR* mutation, it is quite plausible that some cases diagnosed as Young syndrome were in fact CF.

DISORDERS OF IMMUNITY

Immunologic deficiencies are also associated with the development of bronchiectasis. Primary diseases that result in immunodeficiency may devolve from mutations that impair B or T lymphocytes and cause abnormal humoral immunity, cellular immunity, or both. Less frequent anomalies may involve *natural killer* (NK) lymphocytes, neutrophils, or complement proteins. Some specific immune disorders are noted later.

Common variable immunodeficiency, or acquired hypogammaglobulinemia, is the most frequent syndrome recognized in this group of diseases. Clinically, it is seen equally among males and females, distinguishing it from X-linked agammaglobulinemia (Bruton disease), which exclusively involves young males. It may be seen throughout all age-groups, although it is most commonly recognized in early childhood. Although there are normal numbers of circulating B lymphocytes, they fail to differentiate into antibody-producing cells. This results in particular vulnerability to infections with encapsulated bacteria such as *S. pneumoniae*, *H. influenzae*, *S. aureus*, and *P. aeruginosa*. Recurring infections of the airways with these and other organisms frequently result in bronchiectasis (eFig. 48-2).⁶⁴ The diagnosis is established by demonstrating low levels of IgG, absent or markedly reduced IgA levels, and normal or reduced levels of IgM, and the failure to produce appropriate antibody responses following vaccination (normal response is a four-fold or greater increase in specific IgG level 4 weeks after immunization or at least the presence of protective titers if less than threefold increase from baseline). A variant of the hypogammaglobulinemic disorders is selective deficiency of subclasses of IgG, notably IgG2 and IgG4.⁶⁵ Because repletion with gamma globulin is so useful in controlling the recurrent infections, pursuit of the diagnosis of deficient antibody production (common variable immunodeficiency or Bruton disease) is strongly indicated. By contrast, selective deficiency of secretory IgA, another cause of recurrent respiratory infections, cannot be controlled by repletion.⁶⁶

Other, less common primary immune disorders that may result in recurrent or refractory respiratory infections

leading to bronchiectasis include hyper-IgM or hyper-IgE (Job syndrome) and thymic hypoplasia resulting in abnormal cellular immunity (DiGeorge syndrome). There are two forms of the hyper-IgE syndrome: an autosomal dominant form caused by mutations in the *signal transducer and activator of transcription 3* (*STAT3*) gene, resulting in *STAT3* deficiency, and an autosomal recessive form for which the precise genetic cause is not known.⁶⁷ The susceptibility of individuals with dominant hyper-IgE syndrome to pyogenic bacteria and NTM organisms may be due to impaired production of cytokines secreted by type 1 helper T cells such as *interferon-γ* (IFN-γ) and TNF-α, cytokines known to be important in controlling such infections.⁶⁸ Genetic anomalies that may result in combined humoral and cellular impairment include severe combined immunodeficiency syndrome, “bare lymphocyte” syndrome, Wiskott-Aldrich syndrome (an X-linked recessive illness associated with small platelets and eczema), cartilage-hair hypoplasia (associated with short-limbed dwarfism), ataxia-telangiectasia syndrome, and a variety of other rare disorders.

ALPHA₁-ANTITRYPSIN ANOMALIES

Deficiency or anomalies in *alpha₁-antitrypsin* (AAT) may predispose to bronchiectasis. Various phenotypic abnormalities of AAT were described prominently in a recent series of patients seen at the NJH with bronchiectasis associated with NTM.⁶⁹ Previously there had been reports of the relationship between AAT deficiency and bronchiectasis.^{70,71} However, in the great majority of cases in the NJH series, the patients were not deficient in AAT but had heterozygous phenotypes, mainly MS, to a lesser extent MZ, with normal AAT levels. The prevalence of AAT anomalies in the overall cohort of NJH patients with various NTM infections was 17%⁶⁹; even more striking was the 27% prevalence of AAT anomalies in the patients with NTM lung disease due to rapidly growing mycobacteria.⁷² Based on various surveys, AAT anomalies would be anticipated in roughly 8% to 9% of the U.S. population.⁷³ However, the role of heterozygous anomalies of the AAT system in the pathogenesis of lung disease is controversial.⁷⁴ The majority of the NJH patients did not have clinically significant *chronic obstructive pulmonary disease* (COPD) or grossly visible emphysema on CT scanning. Hence we postulate that the AAT anomalies render the patients more vulnerable to respiratory tract infections. Inferential evidence in support of this hypothesis includes an informal survey done among emphysema patients being repleted with alpha₁-proteinase inhibitor (Prolastin)⁷⁵; 74 of the 89 responding patients described a perceptible benefit, and 56 of the 74 identified a reduction in the frequency of infectious exacerbations of their COPD. Possibly relevant to the development of bronchiectasis is the observation that AAT is produced in airway epithelium (as well as the liver) and “Z” AAT may polymerize in the lung and act as a chemoattractant for neutrophils.⁷⁶ Evidence in support of the effect of a direct effect of AAT on infection includes the finding that aerosolized AAT suppresses *P. aeruginosa* lung infection in an animal model^{77,78} and the observation by Shapiro and colleagues⁷⁹ that AAT inhibits replication of the *human immunodeficiency virus* (HIV) in whole blood. Further

support for a direct role of AAT in resistance to infection is the observation in an African population that two polymorphic variants of the AAT haplotype were associated with significantly greater risks for HIV infection when compared with the other nine haplotypes common in sub-Saharan African populations.⁸⁰ Chan and coworkers⁷² showed that AAT inhibits phagocytosis of *Mycobacterium abscessus* by human macrophages, partially denying the mycobacteria their preferred intracellular milieu. It should be noted that a group from France studied AAT alleles in a large cohort of bronchiectasis patients and reached a different conclusion.⁸¹ They found the following phenotypes in their patients: MS, 11.9%; MZ, 3.5%; SS, 1.5%; SZ, 0.5%; and ZZ, 0.5%. In this study the distribution of these phenotypes was not significantly different in their controls, and they inferred that AAT anomalies did not contribute to the risk for bronchiectasis. In a study of 74 patients with severe AAT deficiency (PiZ phenotype), however, remarkably 70 (95%) had bronchiectatic changes on CT scan (eFig. 48-3) and 20 (27%) had clinically significant bronchiectasis, defined as bronchiectasis in four or more bronchopulmonary segments and chronic sputum production.⁸² Thus it appears that if one examines a group of unselected bronchiectasis patients, the prevalence of AAT anomalies is low; however, if one starts with a group with known AAT deficiency, bronchiectasis is commonly found. This observation may be related to the notion that COPD itself may be associated with bronchiectasis as discussed in the next section.

COPD

Over the past decade, likely due to increasing use of HRCT scans, a relatively high prevalence of bronchiectasis has been reported in patients with moderate-to-severe COPD.⁸³⁻⁸⁷ Given the 30% to 60% prevalence of bronchiectasis found in COPD patients in these studies, it would be important to evaluate AAT phenotypes to determine whether the bronchiectasis is associated more closely with severe COPD per se or with associated AAT anomalies. In one study, COPD patients with bronchiectasis had higher levels of the neutrophil chemoattractant IL-8 in the sputa and increased bacterial colonization of the lower airways, and they experienced more severe exacerbations than those without bronchiectasis.⁸⁶ Whether bronchiectasis is a coincident sequela in COPD patients with frequent exacerbations, identifies a subgroup of COPD patients with different pathogenic mechanism, or both, remains to be determined.⁸⁸ Martínez-García and associates⁸⁵ found that, although COPD patients with bronchiectasis had lower FEV₁ and FEV₁/FVC ratio, the presence of bronchiectasis was independently and significantly associated with increased all-cause mortality in multivariate analysis.

CILIATED EPITHELIUM ABNORMALITIES

Congenital structural and functional disturbances of the ciliated epithelial cells are seen in association with bronchiectasis, as well as with frequent and severe upper respiratory tract problems.^{89,90} These disorders appear to be an autosomal recessive process, with an estimated frequency between 1 in 12,500 to 1 in 40,000.⁹¹ PCD embraces a

Figure 48-5 Ultrastructure of the cilia. The structure and function of cilia are elegant and complex. Each ciliated epithelial cell possesses approximately 200 cilia. The direction of ciliary beating is determined by the orientation of the central pair of microtubules. Dysfunction of the ciliary apparatus may involve a variety of structural abnormalities in the cilia or disorganization of the ciliary axes. The cilia beat in a relatively fluidic periciliary medium; above that, adherent by a thin physicochemical junction, is a gelatinous layer of mucus (not shown).

heterogeneous group of ultrastructural deficits involving the axoneme or central functional element of the cilia.⁹² The normal axoneme is composed of nine paired or doublet microtubules arrayed peripherally around two central, single microtubules; attached to the peripheral doublet microtubules are outer and inner dynein arms as well as radial spokes (Fig. 48-5). The direction in which the cilia beat is determined by the orientation of the two central microtubules. In a local sheet of bronchial ciliated epithelium, the axes of the central microtubules are arrayed within a fairly narrow range, typically deviating 25 degrees or less from each other along the long axis of the airway. A variety of abnormalities have been described, including the complete or partial absence of outer or inner dynein arms, a lack of radial spokes, disordered microtubule arrangements, ciliary disorientation, and other rare disturbances. Functionally these disturbances result in reduced or disorganized beating of the ciliated epithelial cells or, in some cases, gross immotility. There may also be inversion of the normal anatomic locations for the organs of the thorax and abdomen, situs inversus universalis or partialis. PCD with situs inversus universalis is known as Kartagener syndrome (Fig. 48-6). In the absence of normal ciliary activity, organ orientation appears random during embryogenesis, resulting in situs inversus in roughly half of the cases. Evi-

dence in support of this theory includes discordant organ orientation in monozygotic twins with disordered ciliary motility.⁹³

The ineffectual beating of the ciliated cells results in stagnation and accumulation of mucus, which classically is associated with early-onset refractory or recurrent infections of the upper and lower respiratory tract, including otitis media, mastoiditis, sinusitis, and bronchitis. Bronchiectasis is a common sequela of PCD, typically involving the dependent zones, including the lower lobes, right middle lobe, and/or the lingular segment of the left upper lobe (Fig. 48-7). Patients with PCD, sinusitis, and bronchiectasis also have a marked tendency toward colonization and infection with *H. influenzae*.⁹⁴ The mechanism(s) for this predilection is unknown, but defective adaptive immunity is a plausible candidate. The ciliary defect also involves the flagella of the spermatozoa, resulting usually, although not universally, in male infertility. Patients may have a history of neonatal respiratory distress, a characteristic early-life complication of PCD.

Diagnosing PCD is often problematic.⁹⁴ Consideration of this diagnosis should be given in the setting of early-onset upper and lower respiratory infections (see earlier). Male infertility, although suggestive, may be due to Young syndrome in a North American population. A suggestive

Figure 48-6 Bronchiectasis: Kartagener syndrome. **A**, Frontal chest radiograph shows dextrocardia with basal predominant linear opacities, the latter consistent with bronchial wall thickening and bronchiectasis. **B**, Axial chest CT shows dextrocardia and severe, cystic bronchiectasis, particularly on the left (arrow). Note the left lung shows a morphologic configuration resembling a right middle lobe (same arrow). Numerous small nodules are consistent with small airway impaction. (Courtesy Michael Gotway, MD.)

Figure 48-7 Dependent-zone bronchiectasis in primary ciliary dyskinesia (PCD). This 35-year-old white woman has classic PCD. She has atelectasis and saccular bronchiectasis involving the right middle lobe, the medial basilar segment of the right lower lobe, and the anteromedial aspects of her left lower lobe. She has previously been treated for *Mycobacterium avium* complex and now has refractory infections with *P. aeruginosa*.

feature on HRCT is predominant bronchiectasis in the lower lobes, with or without right middle lobe or lingular involvement and sparing of the upper lobes (unpublished data). Diffuse, poorly defined flocculent centrilobular opacities in the lower lobes is typical of PCD, reflecting chronic bronchiolitis. Either electron microscopic analysis of the ultrastructure of the cilia or clearly documented ciliary dysfunction via high-speed video microscopy is the gold standard for diagnosis. However, such testing is complicated by the following factors: (1) chronic infection may denude the airways of ciliated epithelium, and (2) chronic infection may damage cilia, resulting in nondiagnostic findings. In one report, computer-assisted analysis was shown to increase the diagnostic yield significantly over conventional transmission electron microscopy for inner dynein arm disturbances.⁹⁵ Direct measurements of ciliary beat frequency or coordination is available only in selected research centers.

Using a ciliary beat frequency of less than 11 beats/sec to determine who should have ultrastructural analysis may result in an unacceptable number of missed cases.⁹⁶ Instead, measurement of the ciliary dyskinesia score—a reflection of the ciliary beat pattern—is a significantly more sensitive and specific screening test for PCD using ultrastructural analysis as the gold standard.⁹⁶ Among males, dysmotile or immotile spermatozoa may be demonstrated, and ultrastructural analysis of the sperm flagella may confirm the diagnosis. The saccharin test has also been employed as an inferential test of ciliary dysfunction. In this minimally invasive test, a particle of sodium saccharin (≈ 1 mm in diameter) is placed on the inferior turbinate, roughly 1 cm from the anterior end of the turbinate to avoid the area covered with squamous epithelium.⁹⁷ The patient remains in the sitting position with the head slightly tipped forward and breathing normally. The time for the subject to taste sweetness—an indication of nasal mucociliary clearance and thus of ciliary function in other parts of the body—is then recorded. In negative (normal) test results, the elapsed time is less than 30 minutes. The primary utility of the saccharin test is to exclude PCD. Abnormal saccharin test results are consistent with, but not diagnostic of, PCD, because individuals with other disorders that result in chronic rhinosinusitis may have denuded their ciliated epithelium or have inflammatory factors that impair ciliary beating. Thus the test should not be done within a month of an upper respiratory infection.

A relatively accurate test for PCD is measurement of nasal *nitric oxide* (NO) levels.⁹⁴ In a large cohort with proven PCD, nasal NO levels were significantly lower than in normal persons or subjects with CF. Of interest, parents of PCD patients had lower-than-normal nasal NO levels, intermediate between controls and patients, despite the absence of clinical disease. Several mutations are known to be associated with PCD in genes, including *DNAI1*, *DNAH5*, and *DNAH11*,⁹⁸⁻¹⁰² that encode axonemal motor proteins, structural and regulatory elements, and cytoplasmic proteins involved in assembly of cilia.^{102a,102b} While genetic testing for PCD is not widely available, it is likely to be the diagnostic test of choice in the not too distant future.

BRONCHIAL CARTILAGE OR ELASTIC FIBER DEFECTS

Cartilaginous “C-rings” are present throughout the entire trachea as well as in the large and medium-sized airways, typically down to the fourth through sixth generations of the ramifying bronchi. The primary functional role of these structures is to maintain airway patency during expiration, including during cough.

Mounier-Kuhn syndrome, or congenital tracheobronchomegaly, is a rare disorder associated with gross enlargement or dilation of the trachea and segmental bronchi¹⁰³ (Fig. 48-8 and eFig. 48-4). The underlying defect is atrophy and even absence of elastic fibers and smooth muscle tissues of the large airways.¹⁰⁴ In addition, primary or secondary atrophy of the connective tissue between the rings may result in outpouchings or diverticula, potentially serving as reservoirs for recurrent infections. Distal to the involved airways, bronchial structures generally appear normal. Clinically, Mounier-Kuhn patients may present in their early years or as late as the fourth decade with recurring lower respiratory infections. In advanced stages, airway collapsibility may result in severe airflow obstruction. The diagnosis is readily made by finding extraordinary dilation of the trachea and central bronchi on CT scans (see eFig. 48-4B-D), with airway dimensions 3 standard deviations greater than normal; for men, transverse and sagittal tracheal diameter greater than 25 mm and greater than 27 mm, respectively, is considered abnormally enlarged,

whereas in women, the respective values are greater than 21 mm and greater than 23 mm. Special considerations in management include positive end-expiratory pressure support and silicone or metallic stenting. Lung transplantation is an option, although unique issues associated with Mounier-Kuhn syndrome include recurrent infections when tracheal diverticula are present and difficulty with bronchial anastomosis due to discrepancy in the airway diameters between the donor and the recipient lungs.

Williams-Campbell syndrome, or congenital bronchial cartilage deficiency syndrome, is another rare disorder that tends to present early in life with recurring infection and bronchiectasis.¹⁰⁵ Familial cases have been reported in this condition, although the precise genetic defect is not known. The absence of cartilage from the segmental to the first few generations of the subsegmental airways is the typical finding in Williams-Campbell syndrome, although more proximal bronchi (lobar and main stem) may be rarely affected as well. There is no evidence that cartilage is deficient in tissues other than the lungs. Characteristic findings on CT scan include more extensive peripheral bronchiectasis than would be anticipated by the clinical history and a more proximal extension of bronchiectasis than usual (Fig. 48-9 and eFig. 48-5). Inspiratory ballooning and expiratory collapse of the airways on chest CT scan is characteristic of Williams-Campbell syndrome.¹⁰⁶ The degree of peripheral airway distortion suggests that this disorder entails more than simply the absence of proximal cartilage. Patients with Williams-Campbell syndrome are particularly

Figure 48-8 Congenital tracheobronchomegaly (Mounier-Kuhn syndrome) with bronchiectasis. This 73-year-old woman has had recurring respiratory infections throughout her adult life, most recently associated with *Mycobacterium avium* complex. **A**, On the posteroanterior view, a massively dilated trachea (arrow) is seen. **B**, The dilated trachea with prominent cartilaginous rings is confirmed on a CT scan (between arrows). **C**, Not only is the trachea enlarged, but the main-stem bronchi are dilated (between arrows). (Courtesy Michael Gotway, MD.)

Figure 48-9 Williams-Campbell syndrome. This 50-year-old man had a lifelong history of recurring respiratory infections and productive cough. The airways are massively dilated with collections of respiratory secretions pooling in some of the cystic spaces. Notable are the normal dimensions of the main-stem bronchi (between arrows).

predisposed to proximal bronchomalacia after transplantation due to the combined effects of cartilage deficiency in the main-stem bronchi plus decreased blood supply to the proximal airways due to loss of collateral circulation of the transplanted lung.¹⁰⁷

CONNECTIVE TISSUE ABNORMALITIES

Among the various formally described heritable disorders of the connective tissues, Marfan syndrome has been reported to be associated with bronchiectasis.¹⁰⁸⁻¹¹⁰ Other lung disorders associated with Marfan syndrome include distal acinar emphysema, cystic degeneration, spontaneous pneumothorax, bullae, apical fibrosis, and a congenital pulmonary malformation known as middle lobe hypoplasia.¹¹⁰ In addition to the airway and parenchymal abnormalities, persons with Marfan syndrome may have various other anomalies, including pectus excavatum, pectus carinatum, scoliosis, straight back syndrome, mitral valve prolapse, and aortic insufficiency with dilation of the aortic root. Two of these conditions, scoliosis and pectus excavatum, are also found often in patients with other heritable connective tissue disorders, including Loeys-Dietz syndrome, Shprintzen-Goldberg syndrome, Ehlers-Danlos syndrome, and cutis laxa.¹¹¹⁻¹¹³

This constellation of findings is reminiscent of the prototypic female patients we and others see with bronchiectasis, most commonly in association with chronic NTM lung disease. Based on analogy to these heritable disorders, we

believe that there may be subtle anomalies or polymorphic variants of connective tissue that predispose to bronchiectasis and/or to NTM infection eventually leading to formation of bronchiectasis. Phenotypic findings that are common among these patients include various combinations of scoliosis, straight back syndrome, pectus excavatum or unusually narrowed anteroposterior chest diameter, pectus carinatum, and/or mitral valve prolapse. In 67 consecutive pulmonary NTM patients seen at the NJH between 1985 and 1987, of whom 43 (64%) were women, pectus excavatum and scoliosis were found to be significantly more prevalent in NTM patients compared to contemporary pulmonary tuberculosis patients (27% versus 9% for pectus excavatum and 52% versus 13% for scoliosis).¹¹⁴ Among a series of 63 patients reported from the National Institutes of Health with NTM lung disease, predominantly manifested by bronchiectasis, careful morphometric studies were performed.⁵⁵ Compared with the women in the National Health and Nutrition Examination Survey database, patients with NTM lung disease were found to be significantly taller and more slender. In addition, pectus excavatum, scoliosis, and mitral valve prolapse were found in excess of expected rates. However, the patients did not have dolichostenomelia (a long, narrow frame), hyperdistensible joints, arachnodactyly, or overt aortic root involvement to suggest classic Marfan syndrome.⁵⁵ Neither do they have the cutaneous or joint abnormalities typical of Ehlers-Danlos syndrome.

A large, prospective study of 103 pulmonary NTM patients (all of whom had bronchiectasis) and 101 uninfected controls well matched for age, sex, and race found that NTM patients were significantly taller, had significantly lower mean body mass index and percent body fat, and had significantly higher prevalence of scoliosis and pectus excavatum than controls.¹¹⁵ In addition, following stimulation of whole blood with various agonists, including live *M. intracellulare*, pulmonary NTM patients had significantly lower mean IFN- γ level than controls but similar levels of other proinflammatory cytokines and chemokines, including TNF- α , IL-1 β , IL-6, IL-8, IL-12, IL-18, and *regulated on activation, normal T-cell expressed and secreted* (RANTES).¹¹⁵ In a follow-up study, unstimulated and *M. intracellulare*-stimulated blood from 20 pulmonary NTM patients and 20 controls were randomly selected from the same two original cohorts and measured for *transforming growth factor- β* (TGF- β).¹¹⁶ In contrast to that seen with IFN- γ , the mean *M. intracellulare*-stimulated TGF- β level was significantly greater in pulmonary NTM patients than controls.¹¹⁶ Whether this reduced production of the host-protective cytokine IFN- γ and/or increased production of the immunosuppressive cytokine TGF- β plays a role in causing NTM lung disease remains to be determined.

Because the thoracic abnormalities such as pectus excavatum, scoliosis, straight back syndrome, and mitral valve prolapse that have been described in a substantial number of patients with NTM lung disease are some of the classic features of Marfan syndrome, we reasoned that perhaps some NTM patients, although not meeting clinical criteria for classic Marfan syndrome, possess a subclinical variant of Marfan syndrome.^{55,114,117,118} Marfan syndrome is caused by mutations of the fibrillin 1 (*FBN1*) gene, with more than 600 different mutations of *FBN1* identified. Because some

mutations may result in a milder Marfan syndrome phenotype,¹¹⁸ we posit that some who possess a lesser variant of *FBN1* gene mutation do not have overt Marfan syndrome but remain at increased risk for NTM lung disease.

Our hypothesis does not identify the “prime factor” in the pathogenesis of the bronchiectasis: do the airways dilate because of an intrinsic structural defect, is there an immune defect that increases the risks for infections that set in motion the coughing and inflammation that lead to bronchiectasis, or are both factors present? The first supposition is that there is a propensity for bronchiectasis due to “weakness” of the connective tissue of the bronchial tree. The observation that fibrillin-1 is part of the extracellular matrix and that bronchiectasis and cystic changes seen in Marfan syndrome may develop without overt NTM lung infection suggests the plausibility of intrinsic vulnerability of the bronchial wall to bronchiectasis. Furthermore, it is also of great interest that Marfan syndrome has been linked to middle lobe hypoplasia¹¹⁰ because the right middle lobe is arguably the most commonly affected lobe in NTM-associated bronchiectasis. The second supposition is supported by the fact that the morphologic anomalies seen with Marfan syndrome have been traced to increased localized production of TGF- β , a cytokine that increases susceptibility to mycobacteria.¹¹⁹⁻¹²² Interestingly, some of the other heritable conditions with overlapping physical features to Marfan syndrome, despite having mutations in entirely different genes—*FBN1* in Marfan syndrome, *TGFBR1* and *TGFBR2* genes in Loey-Dietz syndrome, and *SKI* gene in Shprintzen-Goldberg syndrome—all have in common an increase in TGF- β signaling.¹²³

Could slenderness itself—independent of malnutrition or any underlying illness—predispose individuals to mycobacterial infections? One intriguing hypothesis for the increased susceptibility to mycobacterial infections in thin individuals is that the susceptibility is due to a relative deficiency of leptin, which is normally produced by fat cells. A study of over 100 pulmonary NTM patients and a similar number of uninfected controls demonstrated that the normal direct relationship between body fat and leptin—and the expected inverse relationship between body fat and adiponectin—were preserved in the control subjects, but both relationships were lost in pulmonary NTM patients.¹¹⁵ Experimental corroboration for the leptin hypothesis comes from studies showing that leptin-deficient (Ob/Ob) mice are more susceptible to *Mycobacterium tuberculosis*¹²⁴ and *M. abscessus* lung infections.¹²⁵

In view of the preponderance of females in recent series with bronchiectasis associated with MAC, two theories have been proposed. “Lady Windermere’s syndrome,” named after a character in a novel by Oscar Wilde, posits that women—in the effort to be demure or elegant—voluntarily suppress their cough, leading to accumulation of secretions and chronic infections.¹²⁶ However, it has been our observation that these patients cough frequently.^{127,128} Rather than voluntary suppression, it seems more plausible that their coughing may be ineffectual due to airway collapsibility, which interrupts movement of secretions out of the bronchial tree.

An alternative proposition came from Japan, where they, too, have noted a particular female vulnerability to

bronchiectasis with MAC, largely among elderly, postmenopausal women.¹²⁹ Tsuyuguchi and associates¹²⁹ demonstrated that among female mice, oophorectomy led to higher mycobacterial loads in the lungs and spleen following intravenous challenge with MAC. Furthermore, estrogen repletion normalized the bacillary burden, and ex vivo macrophages supplemented by estrogens were more competent at limiting mycobacterial growth.

However, neither the putative relationship to connective tissue disorders nor the alleged role of estrogen deficiency can explain the high prevalence of females in recent reports of MAC-related bronchiectasis. In these series, 80% to 95% of patients described have been women.^{8,9,15} Certainly, this might reflect referral or reporting bias. Furthermore, we cannot exclude the possibility of sex-associated effects on connective tissue strength/integrity or cellular immunity.

An additional remarkable element of the reported cases of MAC-associated bronchiectasis is the strong preponderance of whites. White females constitute 80% to 95% in recent series, including those compiled in communities/areas with large African American, Hispanic, or other minority populations.^{8,9,15} Again, given the potential for referral, reporting, or ascertainment biases, we cannot be sure of the validity of these observations. However, among the specialists with whom we correspond, this is a strongly held perception. The relatively higher prevalences of CF and AAT anomalies in European-derived populations may partially, but not wholly, explain this apparent imbalance in the white population but would not explain the preponderance of white women in some series.

Fowler and coworkers¹³⁰ compared ciliary beat frequency in epithelial cells obtained from the nasal turbinates of patients with pulmonary NTM disease, PCD, CF, and in healthy normal subjects. Interestingly, they found reduced basal ciliary beat frequency (≈ 2 beats/sec less than normal subjects) and less-than-expected increases in ciliary beat frequency upon stimulation of the epithelial cells with various Toll-like receptor agonists. In contrast, a normal increase in ciliary beat frequency was seen with Toll-like receptor 4 agonist (lipopolysaccharide) stimulation, suggesting that the ciliary defect may be more functional than anatomic. Nasal NO level was also decreased in the pulmonary NTM patients compared to normal subjects; significantly, addition of either a chemical NO donor or a cyclic 3',5'-guanosine monophosphate-specific phosphodiesterase type 5 inhibitor (sildenafil) to the respiratory epithelial cell of pulmonary NTM patients restored their ciliary beat frequency.

CONGENITAL AND DEVELOPMENTAL ANOMALIES

Conditions such as sequestration, agenesis, hypoplasia, and atresia may primarily cause bronchiectasis or may predispose to infections that secondarily cause bronchiectasis. Sequestrations presumably develop because of accessory primordial lung buds, which may be invested within normal lung tissue (intralobar) or external to the normal lungs (extralobar). Sequestrations may or may not connect with the bronchial tree and often derive their blood supply directly from the aorta. Clinically, they most commonly

present with recurrent and/or chronic lower respiratory tract infections beginning in the second or third decade of life. Radiographically, they usually appear as irregular, peculiar densities abutting the diaphragm in the posterior basal regions. Unilateral hyperlucent lung (Swyer-James-MacLeod syndrome) is characterized by unilateral bronchiolitis leading to hyperinflation. In some cases, bronchiectasis is present. The etiology and pathogenesis of this rare disorder are uncertain but may involve developmental or acquired disturbances of the bronchial tree.

IDIOPATHIC INFLAMMATORY DISORDERS

There are a wide array of conditions associated with bronchiectasis that might be included under the rubric of idiopathic inflammatory disorders. They are all systemic illnesses that variably involve the lungs and, in such cases, may or may not result in bronchiectasis.

Sarcoidosis is by far the most common of these disorders. (See Chapter 66 for a comprehensive review.) Broadly, sarcoidosis may involve the airways by several fundamental mechanisms: diffuse parenchymal scarring resulting in traction (eFig. 48-6) and airway distortion, endobronchial granulomatous inflammation including stricture with post-stenotic infection, or compression secondary to hypertrophic peribronchial lymphadenopathy.¹³¹

Rheumatoid arthritis (RA) may entail a variety of pulmonary manifestations. In two early series, bronchiectasis was seen in 3.2%¹³² and 5.2%¹³³ of referral populations of RA patients. More recently, bronchiectasis has been described in considerably higher percentages of RA patients undergoing HRCT scanning: 20% to 35%¹³⁴; surely these studies were skewed by selecting patients with respiratory problems to undergo CT scanning. However, bronchiectasis was seen in 8% of RA patients without respiratory symptoms.¹³⁵ Notably, the majority of the patients in the previously discussed series did not have RA-associated interstitial fibrosis as a presumed cause of the bronchiectasis. Potential causal mechanisms include increased propensity for infections, either intrinsic to RA or secondary to steroid or cytotoxic therapy. Sjögren syndrome in association with RA has also been proposed as a risk factor, but the evidence is inconsistent.¹³⁴ Clinically, it should be noted that the presence of bronchiectasis in RA patients was associated with an unfavorable prognosis in one series.¹³⁶

Ankylosing spondylitis has been classically associated with upper lung zone fibrocystic degeneration (see Fig. 98-16) and ankylosed fusion of the junctions of the ribs and vertebrae, resulting in restricted ventilation. However, in a large series from the Mayo Clinic, pulmonary involvement was described in only 1.2% of the patients (eFig. 48-7).¹³⁷ Bronchiectasis independent of apical fibrocystic disease has been seen in a small series from the United Kingdom.¹³⁸ Ankylosing spondylitis was reported in association with MAC in an early series from the NJH.¹³⁹

Systemic lupus erythematosus may involve an assortment of pulmonary complications, including those intrinsic to systemic lupus erythematosus and others related iatrogenically (see Chapter 65). Bronchiectasis, as such, was described in 21% of systemic lupus erythematosus patients studied with HRCT in one series¹⁴⁰; factors related to bronchiectasis were not well studied. As with RA,

the presence of Sjögren syndrome may be a comorbid element.

Sjögren syndrome, keratoconjunctivitis sicca, and xerostomia (dry eyes and mouth), may exist in the primary form or in association with other collagen vascular diseases such as RA or systemic lupus erythematosus. Pulmonary complications of Sjögren's syndrome include lymphocytic interstitial pneumonia, lymphoma or pseudolymphoma, and/or pulmonary hypertension (see Chapter 65). Bronchiectasis has also been noted.¹⁴¹⁻¹⁴³ It is reasoned that lymphocytic inflammation results in impaired function of mucous glands, in turn resulting in decreased volumes and increased viscosity of mucus. This leads to airway obstruction, poor clearance, and chronic infection. There have not been large surveys employing the CT lung scan in Sjögren syndrome patients to quantify the risk for bronchiectasis. However, we have recently seen several elderly female patients with primary Sjögren syndrome in whom bronchiectasis was prominent.

Inflammatory bowel disease has been related directly to bronchiectasis.¹⁴⁴ Inflammatory bowel disease-associated bronchiectasis appears to be more common with ulcerative colitis than Crohn disease.¹⁴⁵ In the majority of cases, the inflammatory bowel disease antedates the lung manifestations, but in some cases the pulmonary symptoms may herald the inflammatory bowel disease. One unique observation of ulcerative colitis-associated bronchiectasis is that it may develop after therapeutic colectomy.¹⁴⁶ Proposed pathogenic relationships include a cryptogenic infection that incites both airway and intestinal inflammation, common epithelial targets of autoimmunity, or sensitizing agents that are inhaled and/or ingested.

Relapsing polychondritis is identified essentially as progressive inflammation, weakness, and deformity of cartilaginous structures, including the ears, nose, larynx, and tracheobronchial tree, typically associated with nonerosive polyarthritis. In addition, there may be inflammatory and/or functional disturbances of the eyes, auditory/vestibular components of the ears, and aorta (vasculitis with aneurysm). Respiratory involvement is a common clinical element of relapsing polychondritis (tracheal and bronchial cartilage inflammation, resulting airway collapse and airflow limitation) (eFig. 48-8) and a major cause of mortality. Bronchiectasis in such patients may be due to primary bronchial damage and/or recurrent infection.¹⁴⁷

ASPIRATION/INHALATION ACCIDENTS

Spillage of foreign matter into the airways may result in bronchiectasis. There are two fairly distinct scenarios in which such matter might be aspirated into the lungs and cause sufficient damage to result in chronic deformity of the airways. One is the direct spillage of secretions from the oropharynx, infamous for containing a plethora of microorganisms, including microaerophilic and anaerobic bacteria, which can produce necrotizing pneumonia. The other is introduction of materials refluxed from the esophagus and/or stomach, which, in addition to the microorganisms noted earlier, contain food particles, hydrochloric acid, biliary or pancreatic secretions, and microbes indigenous to the gut, including *Helicobacter pylori*.¹⁴⁸

Laryngeal protective functions are imperfect, and “micro-aspiration” is common. Thus we might presume that aspiration leading to lower respiratory tract infections involves greater-than-usual volumes and/or more noxious contents. Also, it is reasonable to posit that once the airways have been damaged, a lesser inoculum can have more substantial clinical effects, a variant of the “vicious circle” theory.

Many factors influence the likelihood/frequency of aspiration. They include (1) depressed sensorium (trauma, alcohol or drug abuse, postictal confusion state, general anesthesia); (2) altered brain-stem function (following cerebrovascular accident, after polio, primary neurologic diseases such as multiple sclerosis, amyotrophic lateral sclerosis, or syringomyelia); (3) altered laryngeal structure/function (after surgery following irradiation); (4) esophageal disorders (dysmotility, obstruction by tumors or strictures, muscular dystrophy, achalasia, tracheoesophageal fistulas, or lower esophageal sphincter incompetence); and (5) gastric dysfunction (dysmotility or outlet obstruction).

Although all of these elements may contribute to the risk for infection (and bronchiectasis), it seems likely that gastroesophageal reflux is the most common factor. Among a cohort of bronchiectasis patients noted previously from the NJH, approximately three fourths of them had demonstrated abnormalities of esophageal morphologic features (dilation and thickening), function (dysmotility), anatomy (hiatal herniation), or competence (overt reflux).¹⁴⁹ Indeed, the frequency of esophageal disturbances was so high that one might question whether the esophageal findings were the cause of recurring infections/bronchiectasis or, in some cases, an effect. In the latter regard, it is important to note that among series of patients with chronic asthma and idiopathic pulmonary fibrosis, the incidence of demonstrated esophageal dysfunction ranged from 80% to 95%.^{150,151} It is plausible that labored breathing with wide disparities between intra-abdominal and intrathoracic pressure and/or chronic coughing, which stresses and dilates the diaphragmatic ring, might disrupt the lower esophageal sphincter and subject the esophagus to distending forces.¹⁵² An additional factor that could contribute to gastroesophageal reflux disease is the medications employed for these pulmonary disorders, including anticholinergics, β_2 -agonists, theophylline, and corticosteroids, all of which impair lower esophageal sphincter function,¹⁵³ and broad-spectrum antibiotics, which alter gastroesophageal flora.

In any case, clinicians should be alert to the potential of gastroesophageal reflux disease/aspiration as having a primary or contributing role in the development of bronchiectasis. For those suspected of disordered deglutition, tailored hypopharyngography employing contrast materials of varying consistency may identify unsuspected aspiration. It is important to note that some patients spill contrast material into their trachea without any awareness or coughing. Such studies may be performed with a speech therapist, who can also aid patients with safer techniques for eating, drinking, and swallowing.

Impaired esophageal motility may be suggested on CT scans of the lungs in which the esophagus is grossly dilated, there is excessive air present along the course of the esophagus, or the walls of the esophagus are thickened. Impaired motility may often be demonstrated on a simple barium swallow. The extent of impaired contractility may be

measured by esophageal manometry; this is critical if reconstitution of the lower esophageal sphincter is contemplated. Demonstrating actual reflux may be problematic. If gross reflux is demonstrated on a routine study, it is sufficient for a presumptive diagnosis. However, if symptoms or other clinical features suggest gastroesophageal reflux disease and the upper gastrointestinal series has negative results, an 18- to 24-hour pH probe with or without measurement of impedance may both identify and quantify reflux episodes.¹⁵⁰ Nonacid reflux may result in chronic cough and even lung injury.¹⁵⁴ Among the implications of these findings is that acid-inhibition measures may not be sufficient to protect the airways. For individuals with evidence of recurrent aspiration, elevation of the head of the bed should be done routinely.

Toxic inhalation or thermal injury may also be associated with bronchiectasis. Acute and chronic inflammation of the tracheobronchial tree, bronchiolitis, bronchiolitis obliterans, and diffuse alveolar damage may be a consequence of exposure to toxic metal fumes (e.g., aluminum, cadmium, chromium, nickel) or toxic gases (e.g., ammonia, chlorine, phosgene, sulfur dioxide) (see Chapter 75). In severe cases, bronchiectasis may ensue because of either infectious complications of the exposure, denuding of the ciliated epithelium, or progressive fibrosis. Similarly, chronic airway damage and bronchiectasis may evolve following thermal or smoke injury.

POSTOBSTRUCTIVE DISORDERS

Foreign bodies may be aspirated into the airways in association with infants and children putting foreign objects in their mouths, choking events while eating, trauma, or loss of consciousness, including seizures. In some cases the obstructing object may be radiopaque (teeth, bone, or metal objects), but in most instances the obstructing material (e.g., peanuts, vegetables) is not discernible by radiographic study. Tumors, benign or malignant, may also result in airway obstruction, poor drainage, recurrent/chronic infection, and bronchiectasis. The more common tumor types include bronchogenic carcinomas (particularly the squamous cell variety), carcinoid tumors (eFig. 48-9), and papillomas. Extrinsic airway compression due most often to hypertrophic lymphadenitis from granulomatous diseases such as sarcoidosis or infections, including tuberculosis or histoplasmosis, may severely narrow or even occlude large airways. In patients with “focal” bronchiectasis (particularly those with disease limited to only one region, one segment, one lobe [see eFig. 48-9], or even one lung), bronchoscopic examination to exclude an obstructing lesion should be performed early if other causes are not evident.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

In acute or subacute *allergic bronchopulmonary aspergillosis* (or other mycoses) (ABPA/M), patients develop mucoid plugs in the medium-sized bronchi. The inflammation and distention typically results in thin-walled bronchiectasis of the central airways (Fig. 48-10; see Fig. 48-3). Central bronchiectasis, often with mucoid impaction, is characteristic of ABPA, and occasionally the mucoid impaction may

Figure 48-10 Bronchiectasis: allergic bronchopulmonary aspergillosis. **A** and **B**, Axial chest CT shows central bronchiectasis (arrows), typical of allergic bronchopulmonary aspergillosis. (Courtesy Michael Gotway, MD.)

Figure 48-11 Allergic bronchopulmonary aspergillosis with bronchiectasis and high-attenuation mucous impaction. **A**, Axial chest CT displayed in lung windows shows focal left upper lobe bronchiectasis (arrow). **B**, Axial chest CT several years following **A**, displayed in soft tissue windows, shows new consolidation surrounding high-attenuation mucous impaction (arrow) in the region of preexisting bronchiectasis. High-attenuation mucus impaction is characteristic of allergic bronchopulmonary aspergillosis owing to the organism's ability to fix metallic ions. (Courtesy Michael Gotway, MD.)

show high attenuation, reflecting the organism's ability to fix calcium salts, iron, and manganese (Fig. 48-11). Although ABPA/M typically is seen in the setting of recurrent/refractory (steroid-dependent) asthma, clinicians should be aware that these episodes may also include fever, malaise, pleuritic chest pain, and cough productive of purulent secretions. Such episodes may be confused with pneumonia, acute bronchitis, and/or exacerbations of simple bronchiectasis, especially if the asthmatic component is absent or minimal. The picture may be particularly obscure if the ABPA/M is present in individuals with CF, a disorder in which ABPA/M is relatively more common. Features mindful of ABPA/M include characteristic findings on CT scanning, eosinophilia, elevated IgE levels, and dramatic responses to corticosteroids.

The other pathway to bronchiectasis is in the setting of long-standing, inadequately controlled ABPA/M. In such cases, extensive fibrosis and airway distortion may evolve because of uncontrolled inflammation. In these cases the patients may acquire secondary airway pathogens including *P. aeruginosa* or other gram-negative bacilli as well as NTM. In these “burned-out” cases, the patients may not demonstrate asthma, eosinophilia, or elevated levels of IgE.

IDIOPATHIC BRONCHIECTASIS

Depending on the extent of evaluation and perhaps referral bias, “idiopathic” bronchiectasis, for which no known predisposition is identified, is estimated to account for 25% to 50% of cases.^{1,155,156} Although the diagnosis of idiopathic

bronchiectasis can be made after known causes of bronchiectasis are effectively excluded, it often has a characteristic phenotype of bilateral lower lobe bronchiectasis and chronic rhinosinusitis.¹ Genotyping studies of class I and class II major histocompatibility complex molecules indicated that allelic polymorphism for *human leukocyte antigen* (HLA)-B (HLA-B5 and HLA-B52), HLA-C (HLA-Cw*03 and especially HLA-C group 1 homozygosity), and HLA-DR/DQ (HLA-DR1/DQ5) are statistically associated with idiopathic bronchiectasis.¹⁵⁷⁻¹⁶⁰ Because NK cells use their “killer cell immunoglobulin-like receptors” to recognize abnormal HLA-C molecules on the surfaces of infected cells, genotypic analysis of HLA-C–killer cell immunoglobulin-like receptor combinations predicted the possibility of increased NK cell activation in the pathogenesis of idiopathic bronchiectasis.¹⁵⁷ However, to the best of our knowledge, functional studies to confirm excessive NK cell activity in patients with idiopathic bronchiectasis have not been done. Nevertheless, this hypothesis is supported by the presence of bronchiectasis in patients with the transporter-for-antigen-presentation deficiency syndrome, a genetic disorder with impaired HLA class I expression and dysregulated NK, $\gamma\delta$ cytotoxic T cell, and CD8⁺ T-cell function. In this disorder the defective HLA class I expression results in increased NK and $\gamma\delta$ T-cell activities because HLA class I normally serves as an inhibitory ligand for these cell types; on the other hand, abnormal HLA class I expression reduced CD8⁺ T-cell function.¹⁶¹

MISCELLANEOUS

There are numerous other causes of bronchiectasis, including such diverse entities as HIV infection/*acquired immunodeficiency syndrome* (AIDS), yellow nail syndrome, or radiation therapy injury.

Among persons with AIDS, bronchiectasis has been identified in a significant proportion of those undergoing CT scans, including children.^{162,163} Obviously this is skewed by the selection of those with respiratory problems for imaging. Presumably the pathogenesis of the bronchiectasis involves severe, chronic, and recurrent infections with a variety of opportunistic pathogens. An additional element that has not been fully addressed is the potential impact of oxidative damage associated with infection or other stressors on the AAT system.^{164,165} Impairment of AAT function may contribute to the accelerated lung damage, including bronchiectasis, in persons with AIDS.^{166,167}

Yellow nail syndrome is an uncommon disorder marked by the triad of yellow, thick, dystrophic nails; chronic lymphedema of the face, hands, and lower extremities; and pleural effusions.¹⁶⁸ Females are more often involved than males; the median age of onset is 40 years, with cases ranging from infancy to the seventh decade. The most prominent pulmonary finding is bilateral exudative pleural effusions.¹⁶⁹ Recurrent sinusitis and lower respiratory tract infections are common.¹⁷⁰ Bronchiectasis presumably evolves because of chronic infection. Contributing factors may entail abnormal lymphatic structure, increased vascular permeability, deficient immunoglobulin production, and/or ciliary dysfunction.

Radiation therapy, typically delivered for carcinoma of the breast or mediastinal tumors including lymphomas,

Figure 48-12 Bronchiectasis in a field of therapeutic x-irradiation. This 68-year-old woman had been diagnosed with a non-small cell carcinoma of the lung. She received radiation therapy to the right hilar region approximately 18 months previously. Her CT scan shows dense fibrosis and bronchiectasis in the radiation field (arrows). Inferior to this process she had a necrotic cavitary process associated with *Mycobacterium avium* complex infection.

may result in profound damage to the central airways. This reaction is not part of the postirradiation bronchiolitis obliterans syndrome but a distinctive condition marked by focal damage to the cartilage and mucosa of the airways leading to patulous distention and irregularities of the major bronchi in the field of irradiation. In our experience, bronchiectasis secondary to radiation therapy for neoplasms has become less common in the recent era when the control of dosage and field has become more refined. In some cases this condition may be recognized by lung parenchymal scarring in the field of irradiation (Fig. 48-12).

DIAGNOSIS

In the great majority of cases, bronchiectasis is recognized in the context of chronic or recurring lower respiratory tract infections (deemed to be “bronchitis” or “pneumonia”) over many months or years. Some bronchiectasis patients in whom wheezing is a prominent element may have been identified and treated as “asthmatic patients” for many years. Occasionally patients come to attention following an episode of hemoptysis. Less frequently, bronchiectasis is identified on CT scans done for other considerations.

Although chest radiography can suggest bronchiectasis with “tram tracks” (Fig. 48-13) or multiple ring shadows (Fig. 48-14), CT scanning is the current diagnostic study of choice. The finding on imaging of atelectasis of the right middle lobe and/or lingula (Fig. 48-15) is highly suggestive of coexisting bronchiectasis and should be investigated by CT scanning in patients with persistent abnormalities and chronic symptoms. Classic HRCT scan findings of bronchiectasis include lack of bronchial tapering, bronchi visible in the peripheral 1 cm of the lungs, and increased bronchoarterial ratio, producing the signet ring sign (see Fig. 48-1A).¹⁷¹

Figure 48-13 “Tram tracks” on the routine chest radiograph in bronchiectasis. **A**, In the right lower lobe are parallel, nontapering shadows, “tram tracks” (arrow), representing bronchiectasis. **B**, The airway is seen as cylindrical bronchiectasis (arrow).

Figure 48-14 Multiple ring shadows on chest radiography in bronchiectasis. **A**, On the posteroanterior view, thin-walled cystic shadowing is seen in the right mid-lung field (between arrows). The trachea and mediastinum are shifted to the right, indicating extensive volume loss. **B**, The lateral view confirms the presence of multiple ring shadows in the mid-zone (between arrows). **C**, CT scan of this 65-year-old white woman indicates severe varicoid bronchiectasis involving her entire right middle lobe and the anterior segment of the right upper lobe.

Figure 48-15 Atelectasis and bronchiectasis involving the right middle lobe and lingula on chest radiographs and a CT scan. This 60-year-old woman has had recurring “pneumonia” throughout life. **A**, Posteroanterior view shows subtle effacement of the right heart border and cardiophrenic sulcus as well as a hazy opacity at the left heart border. **B**, On the lateral view, there are two oblique densities representing the atelectatic right middle lobe (arrow) and lingula (arrowhead). **C**, CT scan demonstrates bronchiectasis and atelectasis of the right middle lobe and inferior segment of the lingula.

Once bronchiectasis has been identified on CT scan, what studies should be performed to help direct management and classify the disease? Certainly, a careful family history may be useful in identifying genetic risk factors; however, the family pattern is rarely specific for a particular disorder unless there is a clear story for CF.

Past medical history and review of systems should focus on the various disorders noted in [Table 48-1](#) and delineated earlier in the discussion of associated disorders and predispositions.

Laboratory testing may variously include the studies noted in [Table 48-2](#). These tests need not all be performed on initial assessment but may be done sequentially, with the more probable disorders being checked initially.

MANAGEMENT

The care of patients with bronchiectasis typically involves many layers, which may be partitioned into five broad components: airway hygiene, antimicrobial treatment, anti-inflammatory therapy, surgery, and miscellaneous. These modalities are delineated in [Table 48-3](#). Although most patients with bronchiectasis require various elements of each of these components to enjoy optimal health, there is not a standard formula for treating this disorder. The great majority of recurrently or chronically symptomatic patients benefit from a regular mucus-clearing regimen and periodic antibiotic therapy. For most patients a pragmatic or “trial-and-error” approach is required to determine individual needs, preferences, and tolerances.

It is important to note that most elements described in this section have not been proved to be efficacious by randomized, controlled clinical trials. Thus meta-analyses (such as the Cochrane Database of Systematic Reviews) generally cannot confirm the benefits or disutility of such approaches.¹⁷²⁻¹⁷⁹ Perhaps because bronchiectasis is such a complex mix of varying conditions and/or has been an underappreciated “orphan” disease, a paucity of systematic research has been directed at this very troublesome disorder.

AIRWAY HYGIENE AND HYPEROSMOTIC AGENTS

Airway hygiene consists of nonantibiotic therapies directed toward mobilizing and eliminating inflammatory secretions from the tracheobronchial tree and from the paranasal sinuses. Modern devices to facilitate airway clearance of secretions include the Flutter valve, Acapella valve, and high-frequency chest compression vests (see [Table 48-3](#)). Also included under this rubric are steps to prevent/limit aspiration of oropharyngeal or gastroesophageal contents into the airways.

Hypertonic saline, 7% twice or four times daily, has been shown to accelerate mucus clearance, decrease exacerbations, and improve lung function in CF patients.¹⁸⁰ However, its role in non-CF bronchiectasis remains to be seen. Inhaled dry powder mannitol appears promising in airway clearance in bronchiectatic patients,^{181,182} although more definitive studies are needed.

ANTIMICROBIAL THERAPY

Antimicrobial therapy historically has been the centerpiece of bronchiectasis care. However, there is no clear consensus on the major questions in this area, including whether treatment should be given on a routine, periodic schedule (“rotating”) or an as-needed basis for clinical exacerbations. In a meta-analysis that studied the use of prolonged oral antibiotics for purulent bronchiectasis, sputum volume/purulence was shown to decrease, but there were no significant beneficial effects in regard to rates of exacerbations, lung function, or death.¹⁸³ There are also limited data on the preferability of empirical selection of an antimicrobial agent or treatment guided by species identification and in vitro susceptibility testing. For patients unresponsive to empiric antibiotics or who experience frequent exacerbations, it appears prudent to obtain comprehensive microbiologic cultures (including for NTM and fungal organisms) and to tailor antibiotics based on the type of organism identified and drug susceptibility profile.

Aerosolized antibiotics also appear promising in treating or preventing exacerbations. Addition of inhaled tobramycin to oral ciprofloxacin for *Pseudomonas*-associated exacerbation of non-CF bronchiectasis showed improved microbiologic outcome; however, there was no additional clinical benefit over ciprofloxacin alone perhaps due to approximately threefold greater incidence of bronchospasm in the tobramycin arm.¹⁸⁴ In patients with CF, inhaled tobramycin twice daily given in alternating months decreased the frequency of exacerbations due to *P. aeruginosa*.¹⁸⁵ Even in patients without CF, inhaled tobramycin was found to be efficacious.¹⁸⁶ In a randomized study of nebulized saline versus gentamicin (twice daily for 12 months) of 65 patients with non-CF bronchiectasis, the gentamicin-treated subjects had reduced microbial burden, airway neutrophils, and sputum purulence.¹⁸⁷ Improved exercise capacity, decreased exacerbation frequency, and better health-related quality-of-life measure were also seen in the gentamicin arm with the caveat that patients were not blinded, suggesting an element of bias may have been introduced.¹⁸⁸ Compared to nebulized saline as a control, nebulized gentamicin given prophylactically for 12 months also showed significant reduction in markers of inflammation in both the airways (IL-8, TNF- α , IL-1 β) and the circulation (intercellular adhesion molecule-1 and E-selectin).²⁵

ANTI-INFLAMMATORY THERAPY

The obvious rationale for using the anti-inflammatory agents in bronchiectasis is that they may reduce the inflammatory cascade, with the goals of reducing symptoms and limiting the progression of disease and decline in lung function. Anti-inflammatory agents that have been examined in bronchiectasis include the *nonsteroidal anti-inflammatory drugs* (NSAIDs), inhaled corticosteroids, and intermittent macrolides to exploit their anti-inflammatory and other nonmicrobicidal activities.¹⁸⁹

NSAIDs

Because prostaglandins may play a role in augmenting airway secretions, the NSAIDs—by blocking the cyclooxygenase pathway—have been studied in bronchiectasis.

Table 48-2 Diagnostic Studies for the Classification and Management of Patients with Bronchiectasis

Test	Comments
ROUTINE, UNIVERSAL STUDIES	
High-resolution CT (HRCT) of the lungs	If bronchiectasis is suspected, chest CT, particularly HRCT, is the definitive test to confirm suspected bronchiectasis. HRCT may help detect subtle airway dilation before bronchial walls are grossly thickened. The distribution of the bronchiectasis often helps in the differential diagnosis of the underlying cause of the bronchiectasis. HRCT may also identify esophageal abnormalities.
Pulmonary function tests (PFTs)	For patients with significant bronchiectasis, comprehensive PFTs, including spirometry, bronchodilator responsiveness, lung volumes, and diffusion capacity, are important studies that aid in management and prognosis. PFTs may also provide useful hints regarding predisposing conditions.
Complete blood count	Anemia may reflect effects of chronic infection or blood loss (consider inflammatory bowel disorders). Leukocytosis may mark severity of infection.
ESR, C-reactive protein	Eosinophilia may suggest ABPA/M. Nonspecific markers of inflammation; very high levels may suggest underlying connective tissue disease or vasculitis.
Routine sputum culture	Antibiotic therapy in bronchiectasis should generally be directed against specific pathogens and guided by in vitro susceptibility. The presence of mucoid strains of <i>Pseudomonas aeruginosa</i> and <i>Staphylococcus aureus</i> may raise suspicions for CF. <i>Stenotrophomonas maltophilia</i> , <i>Alcaligenes xylosoxidans</i> , and <i>Burkholderia cepacia</i> are gram-negative bacilli that may prove problematic pathogens in patients with long-standing bronchiectasis. Isolation of <i>B. cepacia</i> and <i>Helicobacter pylori</i> require special laboratory techniques.
Mycobacterial sputum culture	Environmental mycobacteria such as <i>Mycobacterium avium</i> complex, <i>M. chelonae</i> , and <i>M. abscessus</i> appear to be increasingly common in contemporary bronchiectasis. May be commensal but often are pathogenic.
Fungal sputum culture	Especially in patients with an asthmatic component, the presence of <i>Aspergillus</i> species (or other molds, including <i>Pseudallescheria</i> or <i>Penicillium</i>) may suggest cause.
CT scan of sinuses	Many bronchiectasis patients also suffer chronic rhinosinusitis. The presence of extensive sinus involvement suggests possible CF, immunoglobulin deficiencies, or ciliary disorders. Also, optimal management often entails aggressive sinus care.
SPECIFIC, DIRECTED STUDIES	
Sweat chloride, CF genotyping, and nasal potential differences	For bronchiectasis patients with bilateral disease, sinusitis, and no other identified risk factor, mild variants of CF appear to be relatively common (see text and Chapter 47). Sweat chloride is regarded as the primary screening test for CF, but many adults with CF have borderline or normal results. Nasal potential difference may be useful for identifying CF in equivocal cases (see Chapter 47).
Alpha ₁ -antitrypsin (AAT) levels and phenotype	AAT anomalies appear to be a substantial risk factor for bronchiectasis, especially in white females. Abnormal proteinase inhibitor phenotypes, even heterozygous patterns such as MS, appear to confer risk even with normal levels of AAT (see text). Repletion of AAT may enhance resistance to lower respiratory tract infections.
Immunoglobulin (Ig) levels	Deficiencies of IgG or IgA may promote bronchiectasis; IgG subclass deficiencies may also be a factor. Elevated levels of IgE may suggest ABPA/M or Job syndrome. Hyper-IgM may be associated, as well, with chronic infections.
Ciliary morphologic configuration or function	For individuals with suggestive stories (see text), a nasal ciliated epithelium biopsy with transmission electron microscopy may identify PCD. Other studies, including ex vivo ciliary activity, the saccharin test, or spermatozoa analysis, may aid in this diagnosis (see text).
Nasal nitric oxide (NNO) levels	Patients with documented PCD have significantly lower levels of NNO than normal subjects or patients with CF. ⁹⁴ Although not universally available, such testing may prove highly useful in identifying PCD. Paradoxically, exhaled NO levels have been elevated in bronchiectasis of diverse causes ²¹⁹ except CF.
Barium swallow	Barium swallow may detect disturbed deglutition, esophageal diverticula, obstructing lesions (tumors or strictures), hypomotility, achalasia, hiatal hernias, or lower esophageal sphincter incompetence with reflux. Note that the absence of reflux on a barium swallow does not exclude this problem (see pH probe).
pH probe	For patients suspected of gastroesophageal reflux, an 18- to 24-hour study with a transnasal pH probe may identify, quantitate, and characterize reflux. Obviously medications that inhibit acid production must be stopped before such tests.
Esophageal manometry	For patients being considered for surgical repair of the lower esophageal sphincter, manometry should be performed to determine that the esophagus generates sufficient pressure to propel food and liquids through the tightened sphincter.
Tailored hypopharyngography (TH)	TH is useful in detecting abnormalities of the initial phase of swallowing, deglutition. Persons particularly prone to problems include those with prior strokes, Parkinson disease, bulbar disorders including postpolio syndrome, and those with prior laryngeal or pharyngeal surgery. Even without such risk factors, some patients have gross aspiration without clinical manifestations (choking, coughing).
LESS COMMON, EXOTIC STUDIES	
Collagen vascular disease (CVD) serologic studies	Various CVDs may contribute to the risk for bronchiectasis, including rheumatoid arthritis, ankylosing spondylitis, and systemic lupus erythematosus. Thus, for patients with compatible histories or physical findings, assays for rheumatoid factor, anti-CCP antibody, HLA-B27, and ANA may be useful. CVD serologic studies may also suggest the diagnosis of Sjögren syndrome, particularly SSA/Ro and/or SSB/La.
Schirmer test	For patients with histories suggestive of “sicca syndrome” (dry eyes, dry mouth, oral ulcers), positive Schirmer test results may indicate the presence of either primary or secondary (associated with a CVD) Sjögren syndrome.

ABPA/M, allergic bronchopulmonary aspergillosis (or other mycoses); ANA, antinuclear antibody; anti-CCP, anti-cyclic citrullinated peptide; CF, cystic fibrosis; ESR, erythrocyte sedimentation rate; HLA, human leukocyte antigen; PCD, primary ciliary dyskinesia.

Table 48-3 Elements for Management of Patients with Bronchiectasis

Procedure	Comments
AIRWAY HYGIENE	
Tracheobronchial Clearance Techniques	
Mechanical “valve” devices (Flutter, Pep, Acapella, and others)	A variety of these devices are designed to transmit agitating forces to the airways to loosen and help propel tenacious secretions out of the bronchial passages. By retarding expiratory flow, they may also stent the airways open. For optimal results, respiratory therapists should assess individual patients’ needs and abilities and train them in proper usage.
Postural drainage and chest physiotherapy	For patients with dependent-zone bronchiectasis, positioning in the prone head-down, Trendelenburg, and/or lateral decubitus postures may promote local drainage. This might be optimized by pretreatment with mucus-mobilizing methods (see later) and clapping or vibrating techniques while in these postures.
Therapeutic vest	The pneumatically powered jacket produces high-energy and high-frequency inflation and deflation forces throughout the entire thorax. Of proven utility in CF, ²²⁰ the vest may also be useful with bronchiectasis of other causes.
Mucus-Mobilizing Methods	
Inhaled β_2 -agonists and/or anticholinergic bronchodilators	Inhaled β_2 -agonists may accelerate ciliary beat frequency as well as relieve the bronchospasm present in some bronchiectasis patients. Although the anticholinergic bronchodilators pose a theoretical risk for “drying” secretions, most bronchiectasis patients tolerate them and enjoy modest benefits not provided by β_2 -agonists. ^{221,222}
Hypertonic saline or mannitol inhalation	Nebulizing hypertonic solutions, including saline or mannitol, into the airways appears to aid patients in the clearance of tenacious secretions. ²²³ Hypertonic saline is considerably less expensive than dornase alfa (see next).
Dornase alfa (Pulmozyme)	This product hydrolyzes neutrophil DNA, which contributes to the viscosity of inflammatory secretions. Of proven utility in CF patients, ^{224,225} it was not beneficial in non-CF bronchiectasis in one trial. ²²⁶ Extended administration in CF patients has been shown to reduce neutrophilic inflammation of the airways. ²²⁷ However, we have found it useful in some patients with diagnoses other than CF. It is quite expensive and should be used judiciously.
N-Acetylcysteine (Mucomyst)	Also used primarily in CF patients, it has been generally supplanted by dornase alfa. ²²⁰ Its side effects include airway irritation when used in high concentrations. Given orally in Europe, this approach has not been proved efficacious, nor is it approved in the United States.
Anti-inflammatory Airway Management	
Systemic steroids	Mucosal edema and the production of inflammatory secretions may be partially alleviated by corticosteroids. Randomized, controlled trials in young patients with CF have shown improvements in clinical and physiologic parameters with extended courses of alternate-day steroids. ^{228,229} (See Chapter 47 for details.) However, there were significant adverse effects, particularly on growth rates in males. ²³⁰ Given these and other deleterious effects of long-term systemic steroids, such treatment arguably should be reserved for refractory cases.
Inhaled corticosteroids (ICS)	To avoid some of the complications of systemic steroids, inhaled treatment is a logical approach. Modest evidence of efficacy has been shown in some but not all trials with CF. ¹⁹⁶ ICS may also improve the airway hyperreactivity common among bronchiectasis patients.
Macrolide antibiotics	In addition to their antimicrobial effects, macrolides have demonstrated host defense–modifying activities that include anti-inflammatory effects. ^{148,231} Azithromycin, an azalide, given over many months has resulted in clinical and physiologic improvement among CF patients infected with <i>Pseudomonas aeruginosa</i> . ²³²⁻²³⁴ Chronic, low-dose erythromycin appears clinically useful in patients with non-CF bronchiectasis. ²¹² These effects must be balanced against the considerable expense and potential for producing drug resistance among bacterial and mycobacterial pathogens common to bronchiectasis. (Patients should be screened for mycobacterial infections before use.)
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Among young CF patients, long-term administration of ibuprofen has shown some benefits. ²³⁵ However, these results may not be generalized, and NSAID therapy should be approached cautiously given the potential side effects.
Anti-aspiration Measures	
Anti-GER management	Teaching patients to alter their dietary practices (reduced food and liquid intake in the evening), elevating the head of the bed, or most drastically, providing surgical revision of the LES or hiatal hernia may lessen the risk for recurrent airway soilage.
Improved deglutition	For patients who aspirate on swallowing, changing the consistency of foods or employing maneuvers such as the “chin tuck” may lessen the risk for airway soilage.
Reducing gastric acid	Although lowering gastric acidity with proton pump inhibitors or H_2 -blockers may diminish the symptoms of reflux, it is illogical to think that it should protect against aspiration. Theoretically, lowered acidity of the aspirated matter might result in reduced damage to the lungs; however, it should not be regarded as a lung-protective intervention.

Continued on following page

Table 48-3 Elements for Management of Patients with Bronchiectasis (Continued)

Procedure	Comments
ANTIMICROBIAL THERAPY	
Episodic, targeted antibiotics	Rather than administering “rotating” or “empirical” agents, this approach involves sampling respiratory secretions during clinical exacerbations and employing antimicrobials on the basis of species identification and in vitro susceptibility. Although logically an attractive option, it entails inevitable delays in treatment and may be confounded by the presence of multiple potential pathogens.
Rotating antibiotic therapy	A popular practice, clinicians might treat bronchiectasis patients with a 1 wk/mo cycle of arbitrarily selected antimicrobials such as, for example, amoxicillin, a fluoroquinolone, and a macrolide. There is some evidence of utility for long-term antibiotic therapy ²³⁶ ; however, the potential for selecting for drug-resistant strains is a consideration. Imperfect evidence reported in a recent analysis suggests that patients with chronic <i>P. aeruginosa</i> infection do better with targeted therapy. ²³⁷
Initial empirical followed by targeted antibiotics	This approach offers the advantage of prompt treatment for an exacerbation, followed by a more narrowly focused regimen based on the results of the initial sputum cultures. To be representative, sputum sampling should be done before initiating empirical antimicrobial therapy.
Role of inhaled antibiotics	The model of inhaled tobramycin in controlling pseudomonal infections in CF patients ^{238,239} (see Chapter 47) is an attractive model for non-CF bronchiectasis as well. ²⁴⁰ Certainly, for those patients with chronic or recurrent gram-negative bacillary infections, this approach might be considered. However, our early experience suggests less tolerance of tobramycin in elderly patients.
Therapy for exotic pathogens	Patients may either acquire secondary infections of preexisting bronchiectasis or primarily develop bronchiectasis due to exotic microbes such as environmental mycobacteria or fungi. In such cases, specific therapy may be indicated.
SURGERY	
Resectional surgery	There are no systematic studies of surgical interventions in bronchiectasis. However, anecdotal observations suggest that extirpation of severely damaged lobes may confer considerable benefit. Disease limited to the right middle lobe or lingula may be particularly amenable. ²⁴¹⁻²⁴³ Whether such resections should be done through the lateral thoracotomy or VATS approach is unresolved, although our group strongly prefers the former.
Transplantation	For younger patients with bronchiectasis-associated respiratory insufficiency, the question of transplantation may arise. Based on the model of CF, it is a plausible consideration.
MISCELLANEOUS	
Vaccination against <i>Streptococcus pneumoniae</i> and against influenza	Although not specifically proved in bronchiectasis, this vaccine seems an obvious adjunct. In addition to vaccination, bronchiectasis patients should be considered for antiviral therapy if they develop clinical influenza.
Smoking cessation	A priority for all pulmonary patients.
Alpha ₁ -antitrypsin (AAT) repletion	Among COPD patients receiving AAT repletion, there was a perception of reduced frequency of infectious exacerbations (see text). For bronchiectasis associated with AAT anomalies, repletion might confer protection against recurrent infections.
Oxygen	Patients with bronchiectasis, especially extensive lower lobe disease, may become hypoxemic with exertion or with sleep. Early detection and O ₂ supplementation may improve exercise tolerance and physical conditioning. Nocturnal O ₂ may lessen pulmonary hypertension and delay the appearance of cor pulmonale.
Methylxanthines	Oral theophylline theoretically might augment bronchodilation, enhance mucus clearance, and enhance diaphragmatic contractility. However, the side effects, variable pharmacokinetics including interactions with macrolide antibiotics, and GER-promoting effects make methylxanthines a potential problem for most bronchiectasis patients.
Cromolyn, nedocromil, or leukotriene modifiers	Although these various asthma medications may have some theoretical roles in bronchiectasis, there have been no studies demonstrating efficacy.

CF, cystic fibrosis; GER, gastroesophageal reflux; LES, lower esophageal sphincter; VATS, video-assisted thoracoscopic surgery.

In a double-blind, placebo-controlled study in patients with bronchorrhea due to chronic bronchitis, diffuse panbronchiolitis, and bronchiectasis, inhaled indomethacin significantly decreased the amount of sputum by half as well as the perceived dyspnea.¹⁹⁰ Another mechanism by which indomethacin may help in bronchiectasis is via inhibition of neutrophil chemotaxis and neutrophil degradation of fibronectin, thereby decreasing airway inflammation and purulence.¹⁹¹

In a comprehensive Cochrane Database review of randomized trials of NSAIDs in CF patients, high-dose ibuprofen has been shown to slow the progression of lung disease, especially in children.¹⁹² In contrast, there have been no randomized, controlled trials on the use of NSAIDs in bronchiectatic patients without CF.¹⁹³

Inhaled Corticosteroids

Although some studies show improved symptoms and lung function in CF patients treated with *inhaled corticosteroids* (ICS),^{194,195} others—including a review of clinical trials—have not found ICS to be beneficial.^{196,197} In non-CF bronchiectasis, relatively small studies indicate that ICS provides symptomatic relief (e.g., reduction in dyspnea, cough, and sputum production).¹⁹⁸⁻²⁰¹ High doses of ICS are typically tried in bronchiectasis because of the notion that neutrophils, dominant in bronchiectatic airways, are relatively resistant to the (apoptotic) effects of corticosteroids.²⁰² Although bronchiectatic patients are often treated with β_2 -agonists and ICS based on extrapolation by clinicians of treatment for COPD and asthma, there is limited evidence of their efficacy with bronchiectasis. Martinez-Garcia and

associates²⁰² performed a pilot study comparing high-dose budesonide 800 µg every 12 hours to budesonide 640 µg plus formoterol once daily and found that the combined treatment with the lower dose of ICS resulted in a greater improvement of dyspnea score, health-related quality of life assessment, and reduced ICS-associated side effects such as pharyngeal irritation and dysphonia. Because of the potential risk for pneumonia with ICS use, as has been documented with COPD,²⁰³ it seems prudent to limit the duration of ICS whenever possible, while monitoring closely for worsening respiratory symptoms and function. It is clear that larger studies are needed to determine the benefits and risks of ICS, long-acting β_2 -agonists, or in combination as maintenance treatment or rescue therapy for exacerbations.²⁰⁴

Intermittent Macrolide Therapy

Independent of their antimicrobial properties, macrolide antibiotics hold great promise in inhibiting disease activity in bronchiectasis because of their non-antimicrobial immunomodulatory effects.²⁰⁵ Intermittent macrolide therapy may help in bronchiectasis via different mechanisms, including decreasing chloride diffusion potential gradient across the airway mucosa (resulting in decreased sputum volume), reducing airway levels of the neutrophil chemotactic factor IL-8, inhibiting both neutrophil and *Pseudomonas* migration, suppressing *Pseudomonas* quorum sensing, disrupting the established biofilm layer, and enhancing alveolar macrophage phagocytic ability.^{206,207} Clarithromycin but not amoxicillin or cefaclor was shown to significantly reduce sputum production in patients with chronic bronchitis or bronchiectasis.²⁰⁸ In a study of a small number of patients with bronchiectasis randomized to standard care for 6 months followed by the addition of azithromycin given at a dose of 500 mg twice weekly for 6 months or vice versa, azithromycin significantly decreased the incidence of exacerbations and sputum volume compared with standard care.²⁰⁹ Similar beneficial effects plus improvement in lung function have been shown in various trials using intermittent azithromycin therapy in CF patients chronically infected with *P. aeruginosa* but also in younger CF patients before they have been colonized with *P. aeruginosa*.²¹⁰ In a double-blind study of about 200 CF patients randomized to azithromycin either 250 mg daily or 1200 mg weekly, there were no differences in improvements in lung function, C-reactive protein level, or days hospitalized, although gastrointestinal side effects were more common with weekly therapy.²¹¹ In a double-blind, placebo-controlled trial of approximately 120 patients with non-CF bronchiectasis and a history of frequent pulmonary exacerbations, low-dose erythromycin (400 mg twice daily) for 12 months significantly reduced (1) the number of pulmonary exacerbations overall by roughly one third as well as in those with baseline *P. aeruginosa* airway infection, (2) sputum production, and (3) lung function decline as measured by FEV₁.²¹² However, erythromycin prophylaxis was associated with increased frequency of macrolide-resistant oropharyngeal streptococci.²¹² Two double-blind, placebo-controlled trials of azithromycin 250 mg daily for 12 months or 500 mg thrice weekly

for 6 months resulted in significantly lower rates of exacerbations compared to placebo.^{213,214} In one study, however, there was a nearly threefold increase in macrolide resistance of bacteria in the azithromycin group, as well as significantly higher incidence of abdominal pain and diarrhea, although these gastrointestinal symptoms did not prevent continuation of azithromycin.²¹⁵ In addition to the potential increase in antibiotic resistance in pyogenic bacteria, long-term azithromycin may predispose to drug-resistant NTM infections in patients with bronchiectasis.²¹⁵ In addition, azithromycin has been shown to inhibit autophagy, a normal homeostatic cell process whereby cells recycle nonessential molecules and organelles in times of nutrient deprivation but an increasingly recognized mechanism in the killing of intracellular mycobacteria.²¹⁵ Other potential serious adverse effects of azithromycin include dysrhythmias and cardiac-related deaths, especially in those with underlying risk factors for cardiovascular disease.^{216,216a}

SURGERY

The role of surgery in the management of bronchiectasis is uncertain. No formal systematic studies of the indications and efficacy of resectional surgery have been conducted among patients with bronchiectasis. Traditional indications for resectional surgery have included chronic disabling infection, recurrent infections of intolerable frequency, or irreversible lung damage distal to a foreign body or benign tumor. Life-threatening hemoptysis may also provoke consideration of surgery, although therapeutic bronchial artery embolization may be the initial treatment of choice. A historical adage has been that surgery does not cure bronchiectasis. If true, it is likely due to our evolving understanding that most cases of bronchiectasis are due to innate risk factors that predispose to recurrence. However, surgery may be an appropriate palliative measure in selected cases.

MISCELLANEOUS

Additional measures, such as smoking cessation and vaccination against pneumococcal disease and influenza are appropriate for all patients. Intuitively, these measures seem particularly important for those with bronchiectasis; however, no systematic information is available to confirm their usefulness in this setting. On the other hand, early recognition of exercise and sleep-related hypoxia has demonstrated substantial benefits in regard to morbidity and mortality. As with all individuals, it seems sensible to ensure that patients with bronchiectasis have repleted vitamin D levels because vitamin D has been shown to induce cathelicidin, an antimicrobial peptide.²¹⁷ Recently it was reported that bronchiectasis patients with vitamin D deficiency have more frequent bacterial colonization (especially *P. aeruginosa*), worse airflow, more frequent exacerbations, higher levels of inflammatory markers in sputa, and more rapid decline in lung function over a 3-year follow-up.²¹⁸

Key Points

- Bronchiectasis is defined by the presence of permanent dilation of the medium-to-large bronchi. The main clinical significance of bronchiectasis is recurrent airway infections by bacterial and fungal organisms resulting in chronic cough, sputum, weight loss, and respiratory compromise.
- Most bronchiectasis is due to a combination of host susceptibility factors—which may be overt or covert—and the recurrent infections and the largely neutrophilic inflammatory response that perpetuate the airway injury.
- Whereas localized bronchiectasis is most often due to suboptimally treated bacterial infections, bronchiectasis due to nontuberculous mycobacteria appears increasingly prevalent; bronchiectasis due to nontuberculous mycobacteria is typically seen in postmenopausal women with lingular and right middle lobe involvement but can also be seen in men.
- Bronchiectasis that is more diffuse is generally due to an underlying host disorder such as cystic fibrosis, primary ciliary dyskinesia, Mounier-Kuhn and Williams-Campbell syndromes, common variable immune deficiency, and allergic bronchopulmonary aspergillosis.
- Bronchiectasis has also been associated with extrapulmonary disorders such as ulcerative colitis and collagen vascular diseases. Severe fibrotic lung diseases from any cause may also result in a form of bronchiectasis known as traction bronchiectasis.
- The linchpins in the management of bronchiectasis are the timely institution of empirical antimicrobials to treat the most likely pathogens and diligent airway clearance measures to improve symptoms. For patients unresponsive to empirical antibiotics or those with frequent exacerbations, sputum cultures should be obtained, drug susceptibility determined, and treatment tailored to more objective data. Surgical lung resection should also be considered for patients with severe localized disease that is recalcitrant to medical treatment.

- Anti-inflammatory agents such as nonsteroidal anti-inflammatory drugs, inhaled corticosteroids, and low-dose intermittent macrolides show promise in alleviating symptoms and reducing the rate of disease progression, but definitive recommendations for their use remain to be defined.

Subglottic and Cervical Tracheal Stenosis

INTRODUCTION

The upper airway ranges from the nares to the subglottis and includes diverse anatomic structures with a wide variety of functions. Along with assisting in respiration, the structures of the upper airway contain the nerves for the sensory functions of taste and smell, create a functionally safe swallow by separating deglutition from respiration, and allow for communication through the generation of voice and speech. The nasal cavity has a defined role in filtering and humidifying air for presentation to the lower airway.¹⁻³ The glottis performs the functions of protecting the airway to prevent aspiration, regulating airflow and vocalization. The pharynx and oral cavity assist in these functions by controlling and shaping substances to be swallowed and modulating voiced sounds from the glottis into words and speech. The upper airway is controlled by both voluntary and involuntary mechanisms. Therefore respiratory function can be affected through uncoordinated or inefficient muscular activity, centrally mediated neurologic reflex activity, and/or humoral or immunologic responses. The exact function of some areas within the upper airway, such as the paranasal sinuses, is unclear.

Pathologic changes in the upper airway are often associated with lower airway disease. Swallowing disorders may result in aspiration with inflammatory and infectious complications in the lungs. Chronic inflammation of the paranasal sinuses is frequently associated with asthma.⁴⁻⁷ Long-standing infection in the sinuses has been implicated as a possible reservoir for recurrent pulmonary infection.⁸⁻¹⁰ Laryngeal dysfunction may create symptoms similar to reactive airway disease. Finally, stenosis of the subglottis or cervical trachea is often misdiagnosed as asthma. In this chapter we discuss the anatomy and clinical conditions of the upper airway and their influence on lower airway function.

THE NOSE**ANATOMY, HISTOLOGY, AND PHYSIOLOGY**

The nose represents the initial site of air entry for the majority of respiration. The external nose has important structural components that, when compromised, may inhibit nasal airflow. The nasal dorsum is made up of three structurally distinct subunits (Fig. 49-1). The upper third of the nasal dorsum is supported by the nasal bones. At their distal end, the nasal bones articulate with the upper lateral cartilages in a region known as the keystone area. The upper lateral cartilages define the middle third of the nose. The structure of the lower third, or nasal tip, is defined primarily by the lower lateral cartilages. The nasal septum divides the right and left sides of the nose and provides additional structural support to the lower two thirds of the nose. The quadrangular cartilage forms the anterior septum. The bone of the vomer, perpendicular plate of the ethmoid, and maxillary crest form the posterior and inferior aspects of the septum.

Airflow through the nose may be limited by the cross-sectional area of the external and internal nasal valves (Fig. 49-2). The relationship between the lower lateral cartilage, the septum, and the inferior turbinate largely determines the external valve area. The angle between the upper lateral cartilage and septum impacts airflow through the internal nasal valve. Facial musculature that attaches to the upper and lower cartilages of the nose can widen these principal areas of resistance, enhancing nasal respiration.¹¹⁻¹² Patients with narrowing or structural weakness in these regions may suffer from nasal obstruction. The external and internal nasal valves are frequently the target of nasoseptal reconstructive surgery.

Another common area implicated in narrowing of the nasal cavity and subsequent nasal obstruction is the nasal septum. Deviation of the septum diminishes the cross-sectional area of the affected nasal passage and can

Figure 49-1 Vertical thirds of the nose. The upper, middle, and lower third of the nose are structurally supported by the nasal bones, the upper lateral cartilages, and the lower lateral cartilages, respectively. (From Hafezi F, Naghibzadeh B, Nouhi AH: Applied anatomy of the nasal lower lateral cartilage: a new finding. *Aesthetic Plast Surg* 342:244–248, 2010.)

Figure 49-2 The internal and external nasal valves. The external nasal valve exists at the level of the inner nostril and is formed by the caudal edge of the lateral crus of the lower lateral cartilage, the soft-tissue alae, the membranous septum, and the sill of the nostril. The internal nasal valve accounts for approximately half of the total airway resistance and is bordered medially by the septum, inferiorly by the nasal floor, laterally by the inferior turbinate, and superiorly by the caudal border of the upper lateral cartilage. The junction between the septum and upper lateral cartilage is normally 10 to 15 degrees. (From Howard BK, Rohrich RJ: Understanding the nasal airway: principles and practice. *Plast Reconstr Surg* 109:1128–1146, 2002.)

significantly impact nasal airflow. Most patients have some degree of septal deviation, so anatomic changes in this area must be correlated with clinical findings when determining if a septal deviation would benefit from treatment. Nasal trauma may lead to septal deviations and spurs; many

patients will relate a history of trauma to the nose. Developmental variations are perhaps a more common cause of deviation and spurs of the nasal septum than is trauma. Overgrowth of the quadrangular cartilage may result in bowing of the cartilage or spurs at the junction of the cartilage and bones that make up the nasal septum. Nasal obstruction related to septal deviation may respond either to surgical or to medical treatment. In patients with concomitant turbinate hypertrophy or chronic rhinitis, treatment with intranasal corticosteroids may diminish mucosal swelling and provide an adequate airway despite the septal deviation. Surgery to straighten the septum has few risks and complications and is an effective method for improving the nasal airway in patients with narrowing secondary to septal deviation. Septal deviations have been implicated as a cause for acute or chronic rhinosinusitis. This is a rare cause for inflammatory sinus disease, and caution is advised in diagnosing or treating rhinosinusitis based upon septal findings alone.

Air that enters the nasal sill (or floor of the nose) and passes through the internal nasal valve accelerates as it passes through this area of narrowing. There is also a change in direction of airflow because inspired air shifts from a vertical to a horizontal trajectory at this site. This combination of acceleration and change in flow vector causes the majority of airborne particles to be deposited in the anterior nasal cavity.^{13,14} Airflow through the nose slows as the nasal passages widen beyond the internal nasal valve.

Upon entry into the nasal cavity, the stratified squamous epithelium of the nasal sill quickly transitions to a respiratory epithelium. Located along the lateral nasal wall, the turbinates (or conchae) serve to warm and humidify air passing through the nasal cavity. Rich vasculature, including venous sinusoids, allows the turbinates to enlarge and shrink in response to various stimuli.¹⁵⁻¹⁷ Fenestrated subepithelial capillaries facilitate heat and gas exchange, enhancing humidification during nasal inhalation.¹⁷ Engorgement of the turbinates increases the surface area and mucosal contact with inspired air. The slowing of airflow beyond the internal nasal valve provides prolonged mucosal contact during nasal inspiration and allows efficient humidification and filtration of inspired air so that even at extremes of ambient temperature and humidity, air that reaches the trachea is very close to body temperature and 98% humidity.

The respiratory mucosa of the turbinates contains both goblet cells and seromucous glands. These structures combine to produce a mucus blanket that is mobilized by coordinated beating of this ciliated epithelium. Nasal irritants, microbes, and other particles are swept through the nasal cavity by this mucociliary clearance mechanism to be swallowed, preventing exposure of the lower airways. The lower airways are further protected by immune function within the nasal mucosa. Both the innate and humoral immune arms of the immune system function within the nasal mucosa, resulting in the secretion of immunoglobulins (primarily immunoglobulin [Ig] A)^{18,19} and microbial toxins such as lysozyme and lactoferrin.^{20,21} Emerging evidence suggests that commensal microbes inhabiting the mucosal surface or mucus layer of the nasal cavity contribute to host defense mechanisms within the nasal cavity

through competitive colonization and perhaps immune regulation.²²

The turbinates are dynamic structures that swell and shrink in response to multiple stimuli. Gravity, nasal irritants, allergic response, and autonomic neural input all regulate the blood supply and venous drainage of the submucosal tissue of the inferior turbinate, resulting in marked fluctuations in turbinate size.^{17,23} The size of the inferior turbinate fluctuates alternately on the right and left side as part of the normal nasal cycle.²³ Pathologic enlargement of the inferior turbinate is one of the most common causes of nasal congestion and nasal obstruction.^{24,25}

The tubular structure of the turbinates contributes to a laminar air flow pattern through the nasal cavity.^{26,27} Aggressive resection of the turbinates enlarges the cross-sectional area of the nasal cavity but risks a paradoxical worsening of nasal obstruction. The humidification function of the turbinates can also be lost with resection, resulting in possible dryness and crusting. This constellation of symptoms following turbinate resection has been referred to as “empty nose syndrome.”²⁸ A conservative surgical approach to nasal obstruction due to turbinate hypertrophy is therefore recommended in patients who do not receive adequate relief from medical therapy.

The superior aspects of the nasal septum, middle turbinate, and superior turbinate are lined with olfactory epithelium. Successful olfaction requires that airborne or mucus-soluble particles reach this epithelium. Odorant-specific receptors of the olfactory epithelium send projections intracranially, through the bone of the cribriform plate. Axons from the olfactory epithelium synapse within the olfactory bulb, and these signals are then routed for central processing. Smell disorders may arise from mucosal inflammation and edema that prevent odorant exposure to the olfactory epithelium. This is frequently a reversible condition. Direct viral injury of the olfactory epithelium has also been postulated as a cause for smell loss, which may result in long-term dysfunction.^{29,30}

Sneezing is a nonspecific, involuntary response to nasal irritation. Allergens, microbes, and other nasal irritants may precipitate this reaction when they contact the nasal mucosa and trigger histamine release. The trigeminal nucleus coordinates the sneeze reflex, which involves muscles of the pharynx, larynx, oral cavity, and chest wall. The pressure generated from a sneeze may expel irritants and can contribute to spread of infections conditions. In susceptible individuals, sudden exposure to bright light may trigger the sneeze reflex. This is an autosomal dominant trait impacting approximately one fourth of the human population.³¹

PATHOLOGIC CONDITIONS OF THE NASAL CAVITY

Rhinitis

Rhinitis, or inflammation of the nasal cavity, may result from multiple causes. Rhinitis may be classified by duration (acute versus chronic) and further segregated as allergic versus nonallergic. Acute rhinitis is a self-limited inflammation, most commonly secondary to viral infection. Many of the clinical features of acute rhinitis may result from the

immune response to viral pathogens. Release of inflammatory cytokines and chemokines including *interleukin* (IL)-6, tumor necrosis factor- α , and interferon- γ results in tissue edema, increased mucus production, and vascular dilation.³² The clinical manifestations of these changes are well known as symptoms of the “common cold”: nasal congestion and obstruction, increased nasal drainage, and diminished sense of smell. Nasal irritants, including perfumes, smoke, and cleaning products, can cause a similar constellation of symptoms although typically of shorter duration.

Allergic Rhinitis

Epidemiology. *Allergic rhinitis* (AR) is a common disorder that is estimated to be the sixth most common chronic illness in the United States.³³ The prevalence of AR is 10% to 20% in the United States and Europe.³⁴ There are an estimated 18 million adults in the United States who suffer from AR, resulting in significant health care expenditures.³⁵ A diagnosis of allergic rhinitis adds approximately \$1500 per patient per year in direct health care costs.³⁵ A similar prevalence of AR is evident in children, and AR in this population is associated with a significant decrease in both physical and emotional health, as well as sleep disturbance.³⁶ As many as 13 million Americans in the workforce suffer from AR, and it is estimated that 3.5 million workdays and 2 million school days are lost each year because of this condition.^{37,38} Overall annual direct and indirect costs of AR in the United States have been estimated at \$5 to \$8 billion and \$11 billion, respectively.³⁹

The incidence of allergic rhinitis has been rising over the past 3 decades. One explanation for this is the “hygiene hypothesis”: early exposure to antigens allows for proper immune system development and a reduced risk for allergic rhinitis and other atopic disease.⁴⁰ Recent data suggest that early microbial exposure may be particularly important in the prevention of not only atopic, but also autoimmune disease.⁴¹⁻⁴³

Diagnosis. Allergic rhinitis symptoms may be seasonal or perennial, depending upon the specific allergen. Pollens from trees and grasses are the most common triggers for seasonal symptoms, whereas dust mites and pet dander represent common triggers for perennial disease. Identification of offending allergens may be accomplished through a variety of approaches. Skin reaction to allergens may be measured through either prick testing or intradermal injection using serial end-point dilution techniques. Both of these approaches carry a rare but important risk for anaphylaxis.⁴⁴ Testing centers must have personnel and equipment to deal with such emergencies. Immunoassays for allergen-specific IgE such as ImmunoCAP have largely replaced radioallergosorbent test as an alternative to intradermal skin testing. This approach demonstrates a similar sensitivity as skin testing. Efficacy of both dermal testing and immunoassays is dependent upon proper antigen selection. Knowledge of local flora is particularly important in patients with seasonal allergic rhinitis. This knowledge is also critical in identifying clinically significant allergens. Identification of offending allergens allows counseling of allergen avoidance and may be used to initiate immunomodulatory therapy.

Pathophysiology. Following an initial allergen exposure, inhaled antigens provoke both early- and late-phase reactions in the nasal cavity. The early phase is initiated by the recognition of a specific allergen by IgE subunits on the surface of mast cells and basophils. IgE activation results in antibody cross-linking, which, through a series of downstream mediators, causes degranulation of mast cells and basophils with release of preformed mediators. Histamine is the primary inflammatory mediator released during degranulation. Tryptase release and de novo formation of leukotrienes may also contribute to nasal inflammation and symptoms. Exposure to inflammatory mediators results in marked tissue edema and mucus secretion, which manifests clinically as rhinorrhea and nasal congestion and obstruction, frequently in association with sneezing. These symptoms develop within minutes of allergen exposure.

The late phase of allergic rhinitis typically arises 4 to 8 hours after allergen exposure. Nasal congestion is typically the dominant symptom. Chemoattractants and adhesion molecules released in response to the initial inflammatory mediators promote infiltration of leukocytes, eosinophils, basophils, CD4⁺ lymphocytes, and monocytes. Activation of these cells results in the release of a second wave of inflammatory mediators.⁴⁵ The early- and late-phase reactions in allergic rhinitis mimic those of allergic asthma.

Another important concept in the pathophysiology of allergic rhinitis is that of priming of the immune response. Repeated allergen exposure results in amplification of mucosal hyperresponsiveness. In patients with seasonal allergic rhinitis, the severity of allergic response depends not only on the current pollen count and allergen exposure, but also upon the cumulative exposure for a given allergy season. Because of this phenomenon, severe symptoms of allergic rhinitis may persist late in the allergy season despite a waning pollen count. This increased allergen sensitivity may be secondary to both a neural hyperresponsiveness and amplification of the immune response through recruitment of mast cells and basophils. Immune system priming is not an allergen-specific phenomenon; patients report increased sensitivity to nonspecific nasal irritants, including smoke and perfume.^{46,47}

Association with Asthma. Allergic rhinitis and asthma are linked through both pathophysiology and epidemiology.^{45,47,48} Eighty percent of patients with allergic asthma also suffer from allergic rhinitis. The presence of allergic rhinitis is a risk factor for the future development of asthma. Guidelines suggest screening patients with persistent allergic rhinitis for asthma and evaluating asthmatic patients for rhinitis.^{47,48}

The unified airway theory suggests that inflammatory cell migration from an inflamed area within the airway may impact distant airway locations. In patients with allergic rhinitis and asthma, segmental bronchial allergen challenge results in an inflammatory response not only in bronchi, but also in the nasal cavity.⁴⁹ When treated with intranasal corticosteroids, these same patients demonstrate a decrease in both nasal and bronchial hyperreactivity.^{50,51}

Treatment. There are three modalities of treatment for allergic rhinitis: allergen avoidance, pharmacotherapy, and

immunomodulatory treatments. Recent consensus panels suggest evaluating the severity and frequency of AR symptoms to guide treatment. Severity of symptoms is categorized as mild or moderate/severe as determined by the level of impact on daily activities and sleep disturbance. Symptoms are classified as intermittent if the duration is less than 4 days per week or for fewer than 4 weeks and as persistent if the duration satisfies both of these criteria.⁴⁸ Figure 49-3 depicts a consensus management strategy for allergic rhinitis.⁵² The vast majority of patients are effectively treated with pharmacotherapy and allergen avoidance. Saline irrigation results in modest symptomatic improvement and may reduce the need for medications with more significant side effect profiles. Evidence-based AR treatment recommendations for allergen avoidance, individual medications, and immunotherapy were revised in 2010.⁵³ Allergen avoidance strategies for patients with allergic rhinitis are similar to those for patients with allergic asthma and require identification of offending allergens. Following identification of clinically significant allergens, environmental precautions may be instituted.

Immunotherapy. Although pharmacologic treatment of allergic rhinitis may be quite effective in managing symptoms, immunotherapy offers the only approach known to impact the natural history of the disease. *Subcutaneous immunotherapy* (SCIT) regimens involve once or twice weekly subcutaneous antigen injections with gradual escalation of the antigen dose. This is the most well-studied and commonly used approach in the United States. More recently, *sublingual immunotherapy* (SLIT) has emerged as an option that avoids injection appointments. This approach has been primarily studied and is frequently used in Europe but has not yet been approved for use in the United States. The overall treatment course for SCIT or SLIT is 2 to 3 years.

With repeated allergen exposure, a shift in allergen-specific T cells to a regulatory phenotype results in suppression of type 2 T helper inflammatory cytokines and enhanced production of IL-10 and antigen-specific IgG4. This results in suppression of allergen-specific IgE and mast cells and appears to inhibit antigen capture and presentation to T cells.⁵⁴ This immune modulation may diminish the onset of additional atopic disorders such as asthma in patients with allergic rhinitis.

Systemic responses to immunotherapy are rare and typically mild. Nevertheless, deaths have been reported from anaphylactic response during immunotherapy, and vigilance is required. SCIT has a higher (although still very low) incidence of systemic response than SLIT; SLIT has a high rate of mild local (mucosal) side effects, which rarely impact the treatment regimen.⁵⁵ Practitioners who administer allergy shots require appropriate training and access to emergency equipment to address the rare systemic response. With sublingual administration, patients often self-administer the allergen, and proper patient selection and education is critical. Multiple trials demonstrate efficacy of both SLIT and SCIT; they appear to have similar efficacy, but head-to-head trials are lacking.⁵⁶⁻⁵⁸ Use of SLIT in the United States is limited by a lack of approval of the U.S. Food and Drug Administration and limited insurance coverage.⁵⁹

Nonallergic Chronic Rhinitis

Overall, nonallergic rhinitis is poorly characterized. *Vasomotor rhinitis* is a subgroup of nonallergic patients thought to suffer from aberrant parasympathetic innervation in the nose. Patients frequently note rhinorrhea in association with eating or a change in the weather. This disorder is more common in elderly patients and may respond well to ipratropium nasal spray. Additional non-inflammatory disorders of the nasal cavity, including nonallergic rhinitis with eosinophilia, may improve with nasal steroid treatment. Symptomatic treatment with saline irrigation is another popular treatment for nonallergic rhinitis.

THE PARANASAL SINUSES

ANATOMY, HISTOLOGY, AND PHYSIOLOGY

The paranasal sinuses are aerated cavities within the skull that connect to the nasal cavity. There are four sets of paired sinuses: the maxillary, ethmoid, frontal, and sphenoid sinuses. The sinuses are lined with a pseudostratified, ciliated epithelium. Goblet cells within the epithelium produce mucus, and the coordinated action of the cilia moves this mucus through the sinus cavities and into the nose. Once thought to be sterile, it is now known that bacterial communities inhabit the mucosal surfaces of the paranasal sinuses in both health and disease.²²

The function of the sinuses has not been clearly established. They may serve a protective role in force dissipation with blunt trauma to the head or face. The paranasal sinuses can impact vocal resonance, which may have aided their evolution. The sinuses may allow for enhanced facial aesthetics. They may play a role in mucus production and immune surveillance in the nasal cavity.

The four paired sinuses are named after the bones that they aerate. The maxillary and ethmoid sinuses are the first to develop and are present at birth. The frontal and sphenoid sinuses develop more slowly. A visible frontal sinus is often not present until age 4 or 5, and continued aeration and development persist throughout the teenage years.⁶⁰ Asymmetric aeration of the sinuses is common, particularly in the later-developing frontal and sphenoid sinuses. The frontal sinus may be absent in up to 10% of normal patients.^{61,62} An increased incidence of frontal sinus aplasia and diminished overall paranasal sinus aeration is seen in patients with congenital disorders that impact the sinuses such as cystic fibrosis.⁶³

Mucus produced in the sinuses is propelled into the nasal cavity by coordinated ciliary motion. The maxillary (Fig. 49-4) and sphenoid sinuses are connected to the nasal cavity by discrete ostia, which often have a diameter of no more than 4 mm. The ethmoid sinuses are made up of a labyrinth of small cavities called air cells that sit between the orbit and the nasal septum. The ethmoid sinus typically drains through clefts between air cells rather than discrete ostia. The anterior ethmoid air cells drain through the middle meatus, between the middle turbinate and the lateral nasal wall. The posterior ethmoid cells drain through the superior meatus, between the superior turbinate and lateral nasal wall. The frontal sinus drainage tract is determined by the variable anatomy of the underlying anterior ethmoid air cells and eventually leads to the middle meatus.

Blood supply to the paranasal sinuses is provided through both the internal and external carotid systems. The *sphenopalatine artery* (SPA) is the terminal branch of the internal maxillary artery, which originates from the external carotid

artery. The SPA enters the nasal cavity through the sphenopalatine foramen just behind the posterior wall of the maxillary sinus. The majority of the blood supply to the nasal cavity is provided by the SPA. The blood supply to the superior nasal cavity, and much of the ethmoid system, arises from the anterior and posterior ethmoid arteries. These vessels are branches from the ophthalmic artery of the internal carotid system and typically run within the skull base along the roof of the ethmoid sinuses. All of these vessels may contribute to refractory or “posterior” nosebleeds. Epistaxis originating from the SPA is amenable to embolization or surgical ligation of the SPA. The anterior and posterior ethmoid arteries are not amenable to embolization due to their origin from the ophthalmic artery and the associated risk for blindness. These vessels are amenable to surgical ligation in cases of refractory epistaxis.⁶⁴

PARANASAL SINUS DISEASE

Overall, inflammatory disease of the paranasal sinuses is poorly understood. Sinusitis likely represents a wide variety of pathologic conditions that may cause either acute or chronic inflammation. Paranasal sinus inflammation is almost inevitably accompanied by inflammation of the nasal cavity, or rhinitis. Thus the term *rhinosinusitis* is typically used to describe this condition.

Diagnosis of rhinosinusitis is based upon the presence of both clinical symptoms and objective evidence of sinus inflammation.^{65,66} Table 49-1 demonstrates the diagnostic criteria for acute, chronic, and recurrent acute rhinosinusitis. The duration of symptoms is the primary factor used to differentiate between acute and chronic rhinosinusitis. Acute sinusitis lasts up to 4 weeks. Patients with signs and symptoms for 12 weeks or longer are diagnosed with chronic sinusitis. Whereas the duration of symptoms is used to distinguish between acute and chronic disease, the pathophysiologic features, symptoms, and treatment of these entities are different. Acute rhinosinusitis is most commonly an acute infectious disorder, and patients

Figure 49-4 Coronal CT imaging of the paranasal sinuses. **A**, Normal anatomy including well-aerated maxillary (M) and ethmoid (E) sinuses bilaterally, patency of the osteomeatal complex (arrow), and normal appearance of the inferior turbinates (IT). Incidentally noted is a left concha bullosa (CB), a normal variant involving aeration of the middle turbinate, which occurs in approximately 30% of patients. **B**, CT findings consistent with acute sinusitis. There is unilateral opacification of the ethmoid sinuses (*) as well as a fluid level within the right maxillary sinus (arrows). Acute sinusitis may present with unilateral or bilateral disease and routine CT imaging is not recommended. **C**, Bilateral chronic sinusitis with nasal polyposis. There is complete opacification of the maxillary (M) and ethmoid (E) sinuses bilaterally. Arrowheads demonstrate bilateral nasal polyps; soft-tissue density within the nasal cavity and adjacent to the inferior turbinates (IT).

Table 49-1 Diagnostic Criteria for Rhinosinusitis

Term	Definition
ACUTE	
Acute rhinosinusitis	Up to four (4) weeks of <i>purulent nasal drainage</i> (anterior, posterior, or both) accompanied by <i>nasal obstruction</i> , <i>facial pain-pressure-fullness</i> , or both: <ul style="list-style-type: none"> ■ <i>Purulent nasal discharge</i> is cloudy or colored, in contrast to the clear secretions that typically accompany viral upper respiratory infection, and may be reported by the patient or observed on physical examination ■ <i>Nasal obstruction</i> may be reported by the patient as nasal obstruction, congestion, blockage, or stuffiness, or may be diagnosed by physical examination ■ <i>Facial pain-pressure-fullness</i> may involve the anterior face, periorbital region, or manifest with headache that is localized or diffuse
Viral rhinosinusitis (VRS)	Acute rhinosinusitis that is caused by, or is presumed to be caused by, viral infection. A clinician should diagnose VRS when: <ol style="list-style-type: none"> Symptoms or signs of acute rhinosinusitis are present less than 10 days and the symptoms are not worsening
Acute bacterial rhinosinusitis (ABRS)	Acute rhinosinusitis that is caused by, or is presumed to be caused by, bacterial infection. A clinician should diagnose ABRS when: <ol style="list-style-type: none"> Symptoms or signs of acute rhinosinusitis are present 10 days or more beyond the onset of upper respiratory symptoms, or Symptoms or signs of acute rhinosinusitis worsen within 10 days after an initial improvement (double worsening)
CHRONIC AND RECURRENT	
Chronic rhinosinusitis (CRS)	Twelve (12) weeks or longer of two or more of the following signs and symptoms: <ul style="list-style-type: none"> ■ Mucopurulent drainage (anterior, posterior, or both) ■ Nasal obstruction (congestion) ■ Facial pain-pressure-fullness, or ■ Decreased sense of smell ■ AND inflammation is documented by one or more of the following findings: <ul style="list-style-type: none"> ■ Purulent (not clear) mucus or edema in the middle meatus or ethmoid region ■ Polyps in nasal cavity or the middle meatus, and/or ■ Radiographic imaging showing inflammation of the paranasal sinuses
Recurrent acute rhinosinusitis	Four (4) or more episodes per year of ABRS without signs or symptoms of rhinosinusitis between episodes: <ol style="list-style-type: none"> Each episode of ABRS should meet diagnostic criteria above

From Rosenfeld RM, et al: Clinical practice guideline: adult sinusitis. *Otolaryngol Head Neck Surg* 137(3 Suppl):S1–31, 2007.

present with fever and facial pain as characteristic symptoms. *Chronic rhinosinusitis* (CRS) is primarily an inflammatory disorder in which the role of microbes is not well established. Patients with CRS typically note nasal congestion, thick nasal drainage, and facial pressure, but fever⁶⁷ and pain are uncommon in the absence of acute exacerbations.

Objective findings of rhinosinusitis may be present on routine physical examination during evaluation of the anterior nasal cavity or anterior rhinoscopy. Acute rhinosinusitis may be diagnosed by history and anterior rhinoscopy alone; imaging studies are not recommended for uncomplicated acute sinusitis.^{65,66} Objective evidence of inflammation in patients with chronic sinusitis is often difficult to establish on anterior rhinoscopy, so nasal endoscopy or imaging of the sinuses is often required to establish the diagnosis. *Computed tomography* (CT) (see Fig. 49-4) is the preferred method of imaging for the paranasal sinuses; radiographs of the paranasal sinuses lack sufficient specificity and sensitivity and have little clinical utility.

ACUTE RHINOSINUSITIS

Epidemiology

Acute rhinosinusitis is extremely common and typically of viral etiology. It is estimated that adults suffer two to five episodes of viral rhinosinusitis (common cold) annually. School-age children may suffer 7 to 10 colds per year.⁶⁵ In the United States, upper respiratory tract infection is the

Table 49-2 Microbiology of Acute Rhinosinusitis in Adults

Organism	Range of Prevalence (%)
<i>Streptococcus pneumoniae</i>	20–43
<i>Haemophilus influenzae</i>	22–35
<i>Streptococcus</i> spp.	3–9
Anaerobes	0–9
<i>Moraxella catarrhalis</i>	2–10
<i>Staphylococcus aureus</i>	0–8
Other	4

third most common reason for a primary care provider consultation, with approximately a third of these attributed to acute rhinosinusitis.⁶⁸ Gwaltney and colleagues⁶⁹ demonstrated that 60% of viral upper respiratory infections demonstrate radiologic evidence of inflammation within the ethmoid and maxillary sinuses on CT imaging. This study also highlights the futility of CT imaging for distinguishing between acute viral and acute bacterial rhinosinusitis.

Between 0.5% and 2% of viral rhinosinusitis episodes will progress to *acute bacterial rhinosinusitis* (ABRS).⁶⁵ The proposed pathophysiology is that virally mediated mucosal inflammation and edema result in ciliary dysfunction and obstruction of the sinus ostia. This disruption of mucociliary clearance results in mucus stasis and a vulnerability to bacterial superinfection. The most common organisms seen in ABRS are noted in Table 49-2.

Treatment

Distinguishing the self-limited, viral-induced inflammation of the common cold from ABRs is a challenge often faced by primary care physicians. Clinical guidelines suggest that a detailed history is somewhat effective in making this distinction.^{65,66} Patients who fail to demonstrate significant clinical improvement after 10 days or experience a worsening of symptoms after 5 days of the onset of symptoms, also referred to as “double sickening,” are more likely to suffer from ABRs.⁶⁶ Additionally, facial pain beyond what is expected from a viral upper respiratory infection or evidence of extrasinus extension of infection such as periorbital edema may be used to diagnose ABRs. Although patients who meet these clinical criteria demonstrate decreased duration and severity of symptoms when treated with antibiotics, the magnitude of improvement is relatively small.⁶⁶ For patients with severe symptoms, antibiotic treatment is recommended. In patients with moderate symptoms beyond 10 days or who worsen after 5 days, antibiotic treatment is an option.⁶⁵ Amoxicillin has been recommended as a first-line treatment for uncomplicated ABRs with trimethoprim-sulfamethoxazole encouraged for penicillin-allergic patients.⁶⁶ However, with the emergence of resistant pathogens, the Infectious Diseases Society of America now recommends amoxicillin-clavulanate as first choice in adults, followed by doxycycline or a respiratory fluoroquinolone.⁷⁰ Diagnostic imaging, including both radiographs and CT images of the sinuses, do not adequately distinguish between ABRs and acute viral rhinosinusitis and are not recommended unless extrasinus spread of infection is suspected.^{65,66}

Recurrent acute rhinosinusitis, defined as four or more episodes of ABRs per year, may arise in the context of predisposing anatomic variations, exacerbations of CRS, immune compromise, or without identifiable predisposing factors.⁶⁶ Surgical intervention with widening of sinus ostia and removal of ethmoid septations may decrease the frequency and severity of symptoms.^{71,72} Although uncommon, complications arising from rhinosinusitis are seen more frequently in acute than chronic rhinosinusitis. Infection may spread to the orbit or intracranial cavity, a complication more common in children.^{73,74} Group B streptococcus is the most likely pathogen. Urgent evaluation and treatment, often including surgical drainage of affected sinuses and associated abscesses, is required to minimize the risk for visual loss, seizures, meningitis, and even death.

Invasive fungal sinusitis is a life-threatening condition that develops in patients with significant immune compromise. Diabetics with poorly controlled blood glucose levels and patients undergoing bone marrow transplantation are at highest risk. The diagnosis is suspected in this patient population with the development of facial pain, swelling, cranial neuropathies, or unexplained fevers. Imaging studies (CT and magnetic resonance imaging) are sensitive, but not specific, for invasive fungal sinusitis. The diagnosis is established by biopsy results demonstrating fungal invasion into the sinus tissues. Frozen section of diseased tissue may expedite this analysis. Cultures may be helpful to guide antifungal treatment; the morphologic features of fungal elements seen on pathologic evaluation may also assist in identifying the offending fungi. Extrasinus invasion is most common with mucormycosis. Treatment involves surgical

débridement, systemic antifungal medications, and, when possible, reversal of underlying immune dysfunction. Even with appropriate medical care, mortality for this condition approaches 50%.⁷⁵ Aggressive surgical débridement must therefore be considered in the context of the patient's goals of care.

A slowly progressive, indolent form of invasive fungal sinusitis is seen in patients with less severe immune compromise. Solid organ transplant recipients and patients with chronic corticosteroid use are at risk for this disorder. *Aspergillus* is the most common pathogen. The treatment principles are the same as for patients with acute invasive fungal sinusitis.

CHRONIC RHINOSINUSITIS

Epidemiology

Chronic rhinosinusitis (CRS) has an uncertain incidence because the diagnosis often requires both subjective symptoms and nasal endoscopy or CT evaluation. Surveys, which rely only on patient symptom reports, suggest that more than 15% of the U.S. population suffers from CRS,^{76,77} likely a significant overestimation of the true incidence.⁶⁵ The prevalence of physician-diagnosed CRS using diagnostic coding reporting in a limited geographic area was closer to 2%.⁷⁸ The impact of CRS on overall quality of life is estimated to be similar to that of *chronic obstructive pulmonary disease* (COPD) and congestive heart failure.⁷⁹ In the United States the overall cost burden for chronic sinusitis is estimated at \$8.6 billion/year.⁸⁰

Pathophysiology

CRS is characterized by persistent mucosal inflammation of the paranasal sinuses. The cause of this inflammation is variable and often poorly understood. Numerous theories have been proposed, including systemic immune dysfunction,⁸¹⁻⁸³ staphylococcal superantigens,⁸⁴ pathologic bacterial biofilms,⁸⁵⁻⁸⁷ aberrant immune response to fungus,⁸⁸ and dysbiosis (e.g., imbalance of the resident microbial population).²² Several subtypes of CRS have been well established.

The bacteriology of CRS differs from that of acute sinusitis. *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and anaerobic bacteria are more commonly cultured from patients with chronic disease than with acute disease. Recent studies using culture-independent bacterial identification demonstrate that healthy sinuses contain diverse bacterial communities, which may serve a protective role in the sinuses. Chronically inflamed sinuses are characterized by a loss of bacterial diversity with overgrowth of a pathologic species. *Corynebacterium tuberculostrictum* may represent a previously unrecognized bacterial pathogen. Furthermore, in a mouse model of sinusitis, the pathogenic potential of bacteria is enhanced with depletion of native bacterial communities through antibiotic treatment. Coinstallation of presumed probiotic microbes appears to protect against the inflammatory changes induced by exposure to pathologic bacteria.²²

Association with Allergy and Asthma

The role of allergy and atopy in CRS is unclear. Studies suggest a higher rate of positive skin tests in patients with

CRS⁸⁹ but may be confounded by selection bias. Although a causal role for allergy in patients with CRS has not been demonstrated, treatment of allergy in atopic patients with CRS improves patient outcomes.⁹⁰

CRS with nasal polyps (CRSwNP) demonstrates a more clear association with asthma. Nearly 30% to 40% of patients with polyps describe wheezing and respiratory discomfort. In addition, 26% of patients with polyps report a diagnosis of asthma, compared to 6% of control patients.⁹¹ Patients with asthma also demonstrate a high incidence of sinus mucosal thickening on CT imaging.^{92,93} Although asthmatic patients demonstrate a high incidence of nasal polyps, nonatopic asthma is more strongly associated (13%) with nasal polyps than atopic asthma (5%).⁹⁴ Asthmatic patients who undergo endoscopic sinus surgery for CRSwNP demonstrate clinical improvement in both upper and lower airway disease.⁹⁵⁻⁹⁷

CHRONIC RHINOSINUSITIS WITH NASAL POLYPOSIS

CRSwNP is frequently seen in combination with asthma, and the pathologic findings in these two disorders are similar. Nasal polyp tissue classically demonstrates an eosinophilic infiltrate with a predominance of type 2 T helper inflammatory mediators. CT findings include extensive opacification of the paranasal sinuses and nasal cavities (see Fig. 49-4). Although nasal polyps may be visible on anterior rhinoscopy and may even extend to or beyond the nasal vestibule, more frequently nasal endoscopy is required to visualize nasal polyps. Patients typically present with nasal congestion, obstruction, thick nasal drainage, and anosmia. Facial pressure is common. Severe pain, headache, and fever are unusual in the absence of acute exacerbations of chronic disease. Fatigue and difficulty sleeping are also common symptoms.

Patients with asthma and nasal polyps should be queried regarding sensitivity to aspirin and *nonsteroidal anti-inflammatory drugs* (NSAIDs). Aspirin-exacerbated respiratory disease is found in a subset of CRSwNP patients and is characterized by nasal polyps, asthma, and NSAID sensitivity. Patients with aspirin-exacerbated respiratory disease demonstrate abnormalities in arachidonic acid metabolism, characterized by increased production of proinflammatory

products of the 5-lipoxygenase pathway, and exposure to cyclooxygenase-1 inhibitors, such as aspirin and NSAIDs, results in shunting through the lipoxygenase pathway and in upper and lower airway inflammation. Patients often develop persistent rhinitis in their late teenage years with asthma and sinusitis developing over the next several years. Aspirin and NSAID sensitivity may develop at any point along the course of the disease.⁹⁸ Aspirin-exacerbated respiratory disease represents a significant proportion of patients with asthma (9%)⁹⁹ and CRSwNP (13%).⁹⁴ These patients demonstrate a more refractory clinical course in the treatment of their sinus disease. Aspirin desensitization improves both asthma and sinus disease in this patient population.¹⁰⁰⁻¹⁰³

Patients with unilateral nasal polyps should be evaluated for sinonasal neoplasms with imaging and consideration of biopsy. Before performing a biopsy of a sinonasal mass, the clinician should evaluate the relationship of the mass to the skull base to rule out an encephalocele. Assessment of surrounding vasculature is also critical because both aneurysms of the carotid artery and juvenile nasal angiofibromas may present as a nasal mass. Biopsy of these entities may lead to severe hemorrhagic complications.

Allergic fungal rhinosinusitis (AFRS) is a distinct category of chronic sinusitis. Unlike the majority of chronic inflammatory sinus disease, AFRS is often unilateral. This diagnosis is established by the presence of nasal polyps, eosinophilic mucus with Charcot-Leyden crystals, and skin or blood testing demonstrating allergy to fungus.¹⁰⁴ The incidence of AFRS is higher in African American patients, and the disorder is more common in humid regions, including the southern United States.^{105,106} Bone expansion and erosion may result in initial difficulty distinguishing AFRS from sinonasal neoplasms. In such cases, magnetic resonance imaging findings are also helpful in the diagnosis of AFRS (Fig. 49-5).

Congenital disorders that result in impairment of mucociliary clearance have a high incidence of CRS. Because nasal polyps are unusual in pediatric patients, their presence should trigger evaluation for cystic fibrosis and ciliary dyskinesia. Pathologic evaluation of polyps in these patients is more likely to demonstrate a neutrophilic infiltrate and a predominately type 1 T helper cell-mediated inflammatory process.^{107,108}

Figure 49-5 CT and MRI of allergic fungal rhinosinusitis. Coronal (A) and axial (B) CT images demonstrating allergic fungal rhinosinusitis. Note the extensive expansion of the right maxillary sinus (arrows, A), sphenoid and ethmoid sinuses (arrowheads, B), and right nasopharynx (*, A), with extension of abnormal soft tissue into the medial right orbit (arrowheads, A and B), with destruction of the medial right orbital wall. Note erosion of the skull base (double arrows). Axial T2-weighted MRI (C) demonstrates a loss of signal within the affected sinuses (arrow, right ethmoid sinuses, double arrows, sphenoid sinuses), which is characteristic of allergic fungal rhinosinusitis. (Courtesy Michael Gotway, MD.)

Treatment

Treatment of CRSwNP is challenging. Most patients receive temporary, if any, benefit from antibiotic therapy.^{109,110,110a} Topical steroid sprays often provide improvement^{110,111} but rarely provide adequate symptomatic relief for patients with a significant polyp burden. Systemic steroid therapy frequently provides significant symptomatic improvement.¹¹² Unfortunately, systemic side effects limit long-term use of this medication, and symptoms often recur quickly following cessation of exogenous glucocorticoids. Initial enthusiasm for antifungal irrigations has waned with the publication of trials that demonstrate not only a lack of efficacy, but worsened symptoms when compared to placebo saline irrigations.^{109,110a,113} Endoscopic sinus surgery with removal of polyps and cleaning of mucus and debris from within the sinuses results in significant symptomatic improvement.^{114,114a} Systemic corticosteroids are frequently initiated before surgery for CRSwNP to decrease mucosal inflammation, which improves hemostasis and endoscopic visualization during surgery. Corticosteroids also enhance control of asthma during endotracheal anesthesia and the postoperative period. Even in the setting of appropriately performed endoscopic sinus surgery, recurrence of polyps is common. Combining medical and surgical interventions is critical in this patient population. Surgery enhances postoperative access to the sinuses, allowing enhanced penetration of topical steroid irrigations. Steroid-impregnated implantable materials have also been used to extend the duration of symptomatic improvement following surgery.¹¹⁵⁻¹¹⁷

New biologic treatments hold promise for the treatment of CRS. Omalizumab (anti-IgE) has been used to treat refractory asthma and, although clinical data are limited, early trials suggest that omalizumab may reduce polyp burden and symptoms in CRSwNP patients.^{110,118} Interleukin-5 is an important driver of eosinophil differentiation and survival, and an anti-IL-5 (mepolizumab) has shown promise in early trials as a treatment for CRSwNP.¹¹⁹ A recently completed randomized, controlled trial evaluating anti-IL-4 (dupilumab) as a treatment for refractory asthma demonstrated improvement in CRS symptoms as assessed by a validated, disease-specific CRS outcome score.¹²⁰ Availability and cost currently limit both clinical use and investigational studies into the efficacy of these biologic agents as treatments for CRS.

THE ORAL CAVITY, OROPHARYNX, HYPOPHARYNX, AND LARYNX

ANATOMY, HISTOLOGY, AND PHYSIOLOGY

Oral Cavity

The *oral cavity* is defined as the space from the lips to the end of the hard palate. It contains the teeth, the buccal and gingival mucosa, the mandible and hard palate, the floor of the mouth and the tongue anterior to the circumvallate papilla (Fig. 49-6). The oral cavity structures are mostly under voluntary control. The oral cavity functions to control the ingestion of substances. The structures control

Figure 49-6 Schematic of the oral cavity (green), oropharynx (yellow), and hypopharynx (blue) along with the esophageal inlet, cricopharyngeal muscle, and upper esophageal sphincter.

the substance during mastication and preparation of a bolus suitable for presentation to the oropharynx for reflexive swallowing. This involves the muscles of mastication for opening and closing of the jaws as well as the muscles in the lips and cheeks to control the size of the cavity and the muscles of the tongue to move the food particles around the mouth and shape them into the required bolus. In addition to controlling the intake of substances, the structures in the oral cavity are responsible for voluntary modulation of air exhaled from the lungs. This voluntary control is used to control the rate of the air exhaled, as well as to shape the noises created by air flow into speech and song.

Oropharynx

The *oropharynx* is defined as the space from the end of the hard palate to a plane parallel to the top of the epiglottis (see Fig. 49-6). This space includes the structures of the lateral pharyngeal walls made up by the middle constrictors, the palatoglossus and the palatopharyngeus, the palatine tonsils, the soft palate and uvula, the vallecula, and the base of the tongue. Although these muscles and structures are under voluntary control for assistance in the rate of exhaled air from the lungs and shaping sounds released from the vocal tract, they are under reflexive control for swallowing. Once the sensory nerves are triggered by the exposure to a bolus of solids or liquids, the central nervous system sends a reflexive response to swallow. This reflex results in orderly contraction of the tongue base, soft palate, and lateral pharyngeal walls to propel the bolus posteriorly, seal off the nasopharynx, and propel the bolus to the hypopharynx, respectively. Again, the skeletal muscles of these structures are under both voluntary and reflexive central nervous system control.

Figure 49-7 Schematic view of the larynx with the cartilage and ligamentous structures. The supraglottis, glottis, and subglottic subdivisions are marked. (Modified from Netter FH: *Atlas of human anatomy*, ed 5, Philadelphia, 2010, Saunders. Netter illustration from www.netterimages.com, ID: 1495. © Elsevier Inc. All rights reserved.)

Hypopharynx

The *hypopharynx* is defined as the space from a plane perpendicular to the tip of the epiglottis to the superior and lateral aspect of the larynx down to the esophageal inlet (see Fig. 49-6). This includes the structure of the lateral pharyngeal walls, including the inferior constrictors and mucosal membranes, as well as the bilateral pyriform sinuses. As for the oropharynx, the skeletal muscles that make up these structures are under voluntary control for assisting in regulation of airflow out of the lungs and shaping the airflow into speech as well as reflexive central nervous system control for swallowing. The distal end of the hypopharynx culminates in the upper esophageal sphincter. This is a region of the pharynx that controls opening of the proximal esophagus to allow passage of food into the alimentary track and to prevent the inadvertent regurgitation of food or secretions back into the pharynx and upper airway. Although the upper esophageal sphincter is several centimeters in length, the primary portion is made up of the cricopharyngeus muscle (see Fig. 49-6). This circumferential, slinglike skeletal muscle is maintained in a tonic contracted and closed state. The act of swallowing initiates reflexive inhibition of the neural input, resulting in muscular relaxation. As the larynx and pharynx are pulled upward and forward by the actions of other muscles, the relaxed upper esophageal sphincter is stretched open. This allows the passage of the food bolus. The bolus can fail to pass either because of failure of relaxation of the cricopharyngeus muscle segment or failure to stretch the area open through pull of coordinated muscles on the relaxed upper esophageal sphincter segment. Either will result in the retention of foods and secretions, which can then spill into the upper airway.

Larynx

The *larynx* is made of the bone, cartilage, muscular, and mucosal structures from the epiglottis to the bottom of the

cricoid ring. It is divided into three regions based on the lymphatic drainage patterns. These regions include (1) the supraglottis from the tip of the epiglottis to the top of the vocal folds (also known as the “vocal cords”), including the upper part of the arytenoid; (2) the glottis, which includes the tissue from the top of the vocal fold to 1 cm below the top of the vocal folds; and (3) the subglottis, which is below the vocal fold to the first ring of trachea (Fig. 49-7).

Bone and Cartilage. The structural bone and cartilages of the larynx include the hyoid bone, paired thyroid lamina, and cricoid ring. These structures have ligamentous and cartilaginous attachments to each other to allow them to function as one organ. Specifically, the hyoid is attached to the thyroid cartilage by the thyrohyoid ligament. The thyroid laminae are attached to the cricoid laterally by the fibrous cricothyroid joint and anteriorly by the cricothyroid ligament and membrane. The hyoid bone is attached to the skull base by the styloglossus muscle, the mandible by the geniohyoid muscle, and the tongue base by the hyoglossus muscle. The laryngeal cartilage is attached to the pharyngeal wall through the inferior pharyngeal constrictor muscle and to the cricoid ring by the cricothyroid joint, membrane, ligament, and muscle. The cricoid is attached to the trachea through fibrous attachments. These connections support the airway. Other cartilaginous structures within the larynx include the arytenoid complex cartilages known as cuneiform, corniculate, and arytenoid cartilages and the epiglottic cartilage. The mucosal and muscular structures of the larynx include the aryepiglottic folds connecting the arytenoid complex to the epiglottis, the false vocal folds running from the body of the arytenoid to the base of the epiglottis, and the true vocal folds running from the arytenoid to the thyroid cartilage (Fig. 49-8). The laryngeal ventricle is a cleft between the true and false vocal folds. It contains mucus-producing cells and minor salivary

Figure 49-8 Upper airway anatomy: endoscopic view. A, esophageal inlet; B, arytenoid; C, trachea; D, true vocal folds; E, epiglottis; F, vallecula; G, false vocal folds; H, aryepiglottic folds; I, pyriform sinus; J, interarytenoid region.

glands that lubricate the tissue of the larynx during respiration and voice production. In addition, the shape of the ventricle probably creates turbulence in airflow that is significant for vocal fold vibration during voice production¹²¹ but of relatively little significance for airflow during respiration.

Arytenoid Complex. The arytenoid cartilage is attached to the cricoid ring through a series of anterior and posterior ligaments that form the capsule of the synovial cricoarytenoid joint. The corniculate and cuneiform cartilages have fibrous attachments to the arytenoids and are located on top of and anterior to the arytenoid cartilage, respectively. The true function of these structures is unknown, but they increase and stiffen the aryepiglottic fold and may therefore aid in prevention of aspiration during swallowing. The cricoarytenoid joint allows movement of the arytenoid on the cricoid ring for vocal fold abduction and adduction, which is controlled by the action of the intrinsic laryngeal musculature on the arytenoid. Specifically, the lateral cricoarytenoid muscle attaches from the lateral aspect of the cricoid to the muscular process on the posterolateral aspect of the arytenoid. Contraction of the lateral cricoarytenoid muscle creates inward rotation of the arytenoid on the cricoid and closes the laryngeal airway during swallowing, voicing, and respiration (exhalation). This activity is supplemented by the action of the interarytenoid muscle, which runs between the upper bodies of the arytenoids and pulls the arytenoids together. The interarytenoid muscle is probably more important during voice production than during respiration. The posterior cricoarytenoid muscle attaches from the posterior aspect of the cricoid ring also to the muscular process on the posterolateral aspect of the arytenoid. Contraction of the posterior cricoarytenoid muscle creates outward rotation of the arytenoid on the cricoid and opens the airway during respiration (inspiration).

Epiglottis. The epiglottis has ligamentous attachments to the hyoid bone (hyoepiglottic ligament) and thyroid

cartilage (thyroepiglottic ligament) and fibromuscular attachments to the arytenoid complex (aryepiglottic fold). As the names of these attachments imply (origin to insertion), the epiglottis moves in relation to these supportive structures during respiration and swallowing. This movement is passive. As the tongue base and pharyngeal walls contract and the hyoid and attaching laryngeal supporting framework are pulled upward, the epiglottis tilts posteriorly (passive inversion) to cover the top of the airway and divert the bolus to be swallowed to the outside of the larynx. The epiglottis does not completely cover the airway, but rather steers the bolus through the pyriform sinus and outside of the laryngeal airway. Patients who lose their epiglottis secondary to cancer treatment can be taught to swallow again by strongly contracting the tongue base to pull the larynx forward and partially cover the laryngeal airway. Usually this results in a small amount of residue deposited on the top portion of the larynx and/or vocal folds that then must be cleared out of the larynx into the hypopharynx with a throat clear or cough and swallowed a second time. This is known as a “supraglottic swallowing technique” and is useful in preventing aspiration in cases of epiglottic loss or malfunction.

Mucosal and Fibromuscular Structures. The mucosal and fibromuscular structures include the aryepiglottic folds, false vocal folds, and true folds. As stated previously, the aryepiglottic folds run from the arytenoid complex to the epiglottis. They separate the pyriform sinus of the hypopharynx from the supraglottic larynx and form a sling of tissue around the vocal folds to prevent aspiration during swallowing. They consist of fibrofatty tissue and contain minor salivary glands and mucus-producing cells. If a significant portion of the aryepiglottic fold is removed during surgery, then the liquid or food bolus can fall into the larynx and increase the risk for aspiration. At the inferior portion of the aryepiglottic fold is the false vocal fold. This is a fibrofatty collection of tissue also covered with epithelium and contains minor salivary glands and mucus-producing cells. The true function of the false vocal folds is unknown, but they most likely affect the resonance characteristics of the voice rather than have any effect on respiration or deglutition. The aryepiglottic folds and false vocal folds are part of the supraglottis and can be covered with either respiratory epithelium or squamous epithelium.¹²²

The true vocal folds are composed of the *thyroarytenoid* (TA) muscle covered with mucosa. The mucosa is a stratified squamous epithelium supported by a specialized submucosa or lamina propria that differentiates into three layers. This differentiation is likely secondary to use of the vocal folds for phonation, which causes the supporting fibroblasts to produce and secrete proteins and carbohydrates.¹²³ These extracellular particles are then layered in a particular order with dense collagen as the deepest layer, an elastin-rich middle layer, and glycosaminoglycans and glycoproteins forming a spongy superficial layer. The middle and deep layer form a transition zone known as the vocal ligament, which runs from the anterior aspect of the thyroid cartilage to the vocal process of the arytenoid. This ligament allows the superficial layers to separate from the deeper layers as the vocal folds vibrate to produce voice and is probably responsible for the relatively wide vocal pitch

range that humans are able to produce. The TA muscle runs from the anterior aspect of the thyroid cartilage and attaches along the body of the arytenoid cartilage. As the TA contracts, it adducts, tenses, shortens, and thickens the vocal fold. This is important because, as the TA muscle changes tension and shape, it has an indirect effect on the vocal fold mucosa, which is involved in vocal fold vibration. The vibration frequency of an object is related to the driving force for vibration as well as the tension and mass of the object. Therefore, as we adjust the tension in the vocal fold, through voluntary contraction of the intrinsic skeletal muscle of the larynx, we affect the frequency of vocal fold vibration, which is perceived as the pitch of the voice. In the case of vocal fold tension and mass, the two most important muscles are the TA along with the cricothyroid muscle. As the cricothyroid muscle, which originates on the cricoid ring anteriorly and inserts on the thyroid cartilage, contracts, the thyroid cartilage is subluxed on the cricoid ring. This results in stretching the vocal fold and increasing the tension, which drives up the frequency of vibration and the pitch of the voice.

Pathophysiology. As can be inferred from the previous section, the pharynx and larynx have prominent and complex functions in the upper airway to separate the alimentary tract from the respiratory tract for human survival. For swallowing and respiration the pharynx and larynx must work in a coordinated manner. If these systems fail to function properly, then the airway can be obstructed or pharyngeal contents can be aspirated and potentially lead to lung disease.

DISORDERS OF SWALLOWING

Epidemiology

Disorders of swallowing caused by either neurologic or muscular diseases interrupting the normal sequences of upper airway and pharyngeal activity can lead to the aspiration of pharyngeal contents either directly, during the swallowing act, or indirectly from refluxed gastric contents. Aspiration of large quantities of liquid material or of large solid substances can lead to airway obstruction with asphyxiation and death. Acute aspiration of small amounts of substances has been shown to produce acute pulmonary inflammation.¹²⁴ Aspiration of acidic materials appears to be more inflammatory than aspiration of less acidic materials.¹²⁵ If the aspiration is an isolated single event, then the inflammation resolves with little consequence.¹²⁴ However, repeated aspiration can damage the alveolar lining of cells and capillaries and lead to bacterial invasion, mucosal desquamation, and mononuclear cell inflammation.¹²⁵ In lung transplant patients, chronic aspiration of refluxed gastric contents has been associated with increased failure rates of grafts through the development of bronchiolitis obliterans syndrome.¹²⁶ Although the exact mechanism is unknown, it appears to be related to fibrosis that develops as a response to chronic repeated inflammation. This response may be reduced through the use of agents that reduce inflammation.¹²⁷

Disorders of swallowing, commonly called dysphagia, affect between 2% and 11% of the general population.¹²⁸

The etiology is varied. Dysphagia may arise in response to normal aging due to weakening of the pharyngeal musculature. Neurologic disease, such as stroke, motor neuron disease, or Parkinson disease may cause dysphagia due to mistiming of the swallow with poor coordination, as well as secondary to weakness or spasticity of the pharyngeal musculature. Finally, dysphagia often results from medical intervention for the treatment of head and neck disease or following intubation for respiratory failure.

Dysphagia is reported to develop in 40% to 50% of patients intubated for more than 48 hours.¹²⁹⁻¹³¹ Furthermore, the incidence of postextubation dysphagia rises by 14% for each additional day of intubation and is significantly more common in older patients.^{130,132} The cause of dysphagia due to prolonged intubation is not completely understood. However, because the incidence is remarkably high, all patients intubated for prolonged periods should be evaluated with at least a bedside swallow examination before the initiation of oral feeding after extubation.¹²⁹ Clinical studies have also revealed that aspiration after extubation from prolonged intubation may be silent due to changes in laryngeal and pharyngeal sensation; therefore some authors recommend more aggressive intervention with flexible endoscopic examinations.¹³² Although dysphagia with aspiration does not always lead to pneumonia,¹³² dysphagia alone is correlated with prolonged hospital stays.¹³¹ The incidence of postintubation dysphagia can be reduced by using smaller endotracheal tubes and with careful monitoring of the endotracheal tube cuff pressure.^{133,134}

Symptoms of Disorders of Swallowing

The most common symptoms in patients with disordered swallowing are chronic coughing, weight loss, and repeated episodes of pneumonia. On questioning, patients report that they cough during meals. In general, a greater difficulty with swallowing liquids is indicative of neurologic dysfunction or muscular weakness, and a greater difficulty with solids is more indicative of obstruction. The examiner should inquire about what substances cause the most difficulty, the timing of the cough in relation to eating, the length of time required to finish a moderate-sized meal, and where food appears to create the greatest difficulty during the swallow.

Coughing early during the act of swallowing indicates poor oral motor control of the bolus. Patients with neurologic disorders may notice that they cannot control the food within the oral cavity and the food prematurely spills into the oropharynx or hypopharynx before the patient is ready to swallow. Patients find that substances that break apart easily or consist of both liquids and solids are most difficult because portions of the bolus can escape. Coughing during or after the swallow is most indicative of pharyngeal dysfunction due to either disordered reflex timing of the pharyngeal contraction or muscular weakness that prevents the bolus from moving through the pharynx as required.

Prolongation of mealtimes often leads to malnutrition and weight loss. Patients with an intact swallow mechanism can usually finish a complete meal in 15 minutes. Longer mealtimes are suggestive of dysphagia. When patients go beyond 30 minutes for a meal, they typically begin to lose interest in eating. In most cases, this prolongation is socially

unacceptable, and dining companions begin to leave the table, forcing the patient to stop eating.

Dysphagia can be roughly divided into pharyngeal phase dysphagia and esophageal phase dysphagia. Patients with pharyngeal phase problems will complain of substances sticking in the back of their “throat” and coughing, because of aspiration of retained substances, whereas patients with esophageal phase disorders will complain of food lodging in the chest that needs to be regurgitated or “washed down” with liquids. Cough may also be stimulated at the distal esophagus, but this is after the swallow, nonproductive, and not associated with the development of pneumonia.

Evaluation of Dysphagia

Evaluation is best done by a team of physicians and speech-language pathologists interested in disorders of swallowing. After a careful history the patient can be given a sip of water during palpation of the laryngeal complex. As the patient swallows, the larynx should elevate briskly about 2 cm. In addition, the patient should not cough and should then be able to speak without a wet-sounding voice. If the patient passes this initial screening, then he or she should be asked to take multiple sips to see if the swallowing reflex breaks down. Next, complete head and neck evaluation, and indirect endoscopy of the hypopharynx and larynx is undertaken to assess for lip and tongue mobility and strength and for patterns of retained secretions or food particles. Patients with normal tongue function should be able to protrude the tongue and move it side to side without associated movement of the mandible. Retention of food particles within the oral cavity or inability to move the tongue freely is indicative of weakness or restricted motion. Indirect endoscopy identifying pooling at the base of the tongue within the vallecula is suggestive of weakness of the tongue base, pooling of secretions within the pyriform sinuses is indicative of pharyngeal weakness, and pooling of secretions in the esophageal inlet is indicative of failure of cricopharyngeal opening or obstruction of the esophagus.

To confirm these patterns of weakness, flexible endoscopic evaluation of swallowing¹³⁵ or modified barium swallowing examination can be performed. These tests are usually performed by a qualified speech-language pathologist. Rather than just being a screening test for aspiration, these examinations should be used to identify which deficits within the swallowing act are responsible for the dysphagia. This information will direct treatment strategies.

Treatment

Treatment for disorders of swallowing involves precise identification of the region and type of the swallowing deficit. If muscular weakness is identified, patients can be given a series of exercises that target specific areas of either the tongue base^{136,137} or lateral pharyngeal walls.¹³⁸ If neurologic deficits are identified that result in reflex timing issues or if the muscular deficits are insurmountable, then patients can be taught compensatory strategies to improve the safety of the swallow. These strategies include repositioning of the patient during the swallow so that the bolus is less likely to fall into the airway, chin tuck to keep the bolus in the mouth during mastication, or head turning to close off the weakened side of the pharynx during the swallow act. Finally, if

none of these techniques are beneficial, and the patient and the family are interested, a feeding tube can be inserted to prevent weight loss and lessen the burden of needing to ingest a sufficient amount of calories orally to maintain weight. If repeated aspiration persists, then laryngotracheal separation should be considered.

GASTROESOPHAGEAL AND LARYNGOPHARYNGEAL REFLUX DISEASE

Association with Asthma and COPD

The relationship between reflux disease and asthma and COPD is complex. Although the association between reflux and severe asthma is well accepted, the empirical evidence for causation of one by the other is lacking. Lung disease may be related to reflux disease by different mechanisms. First, direct microaspiration of contents refluxed into the pharynx on a chronic basis may lead to pulmonary remodeling. The extent of injury is related to the amount and characteristics of the aspirate, the frequency of aspiration, and the effectiveness of protective lung-clearance mechanisms. This is the proposed mechanism for the development of bronchiolitis obliterans syndrome in transplant patients. Second, reflux or reduced clearance of food from esophageal dysmotility may cause vagally induced bronchospasm. Vagally induced bronchospasm is associated with increased acidification of the lower esophagus and may be ameliorated by deacidification of the gastric contents in patients with difficult-to-control asthma.¹³⁹ Treatment with a *proton pump inhibitor* (PPI) improves asthma control in individuals with symptomatic *gastroesophageal reflux disease* (GERD), but not in those without symptoms.^{140,141}

However, as previously stated, the association between reflux disease and lung disease does not prove causation. It is possible that the medications for the treatment of asthma increase reflux or that changes from chronic lung disease increase reflux as well. Albuterol is known to lower the resting pressure of the lower esophageal sphincter and decrease esophageal contraction amplitude. These changes may increase the incidence of reflux.¹⁴² Prednisone, which is often prescribed in patients with difficult-to-control asthma, has been shown to increase esophageal acid exposure times.¹⁴³ Chronic lung disease can lead to hyperinflation with flattening of the diaphragm. The diaphragm, specifically the crura around the esophageal hiatus, forms a critical part of the lower esophageal sphincter. Therefore flattening of the diaphragm decreases the protective reflux barrier of the diaphragm. An increased transdiaphragmatic pressure gradient, as seen in patients with COPD, predisposes to the movement of gastric contents into the esophagus.

Evaluation of GERD and Laryngopharyngeal Reflux Disease

There are no universally accepted physical findings in the oral cavity and oropharynx that are pathognomonic for extraesophageal reflux disease.¹⁴⁴ In addition, although attempts have been undertaken to develop a “reflux finding score” for physical changes in the larynx in patients with presumed extraesophageal reflux,¹⁴⁵ attempts at validation of these findings through correlation with pH manometry

have been unsuccessful. It is widely believed that any source of irritation, reflux or otherwise, can lead to the same changes. Therefore the findings previously ascribed to laryngeal reflux disease are nonspecific.

Therefore, after a careful history for symptoms of both classic GERD and extraesophageal reflux disease has been completed, most patients will be placed on a trial of antireflux medications. If the trial results in amelioration of the symptoms, then the symptoms are commonly believed to be secondary to reflux disease. This method of evaluation for reflux with an empirical trial of medications is problematic because there may be a considerable placebo effect. Meta-analysis of randomized controlled clinical trials has shown that the effect of medications in alleviating symptoms is not significantly different from the effect of placebo.¹⁴⁶ Some clinicians proceed to 24-hour pH monitoring and/or impedance testing. Although 24-hour pH analysis is considered the gold standard for esophageal reflux, there are no universally accepted tests for the diagnosis of extraesophageal reflux. Even if attempts are made to measure pH within the hypopharynx to assess for extraesophageal spillage of gastric contents, widely accepted normative data do not exist, and there is significant debate as to what constitutes an abnormal finding.¹⁴⁷

Treatment of GERD

Treatment of GERD or extraesophageal reflux disease causing pulmonary problems is best started with dietary modifications and twice-daily PPI medications. The rationale for these aggressive management strategies is that the pharynx, larynx, and trachea have few if any natural protective mechanisms for the neutralization of aspirated gastric contents.^{148,149}

If there is strong suspicion of GERD or extraesophageal reflux causing pulmonary disease, then consideration can be given to surgical therapies such as Nissen fundoplication. Studies evaluating the true response of symptoms from extraesophageal reflux disease to surgical intervention show conflicting results. This is due in part to the significant difficulty in diagnosing extraesophageal reflux accurately as well as in understanding the role extraesophageal reflux may play in the pulmonary disease process.¹⁵⁰ The best results are obtained when classic GERD is identified and surgery, Nissen fundoplication, is performed for significant reflux within the lower esophagus.¹⁵¹⁻¹⁵³

PARADOXICAL VOCAL FOLD MOTION DISORDER AND LARYNGOSPASM

Definition and Diagnosis

Also known as vocal cord dysfunction, *paradoxical vocal fold motion disorder* (PVFMD) is a descriptive term for inappropriate adduction of the vocal folds during inspiration. The mistimed vocal fold closure creates difficulty breathing and is often misdiagnosed as asthma. The diagnosis of PVFMD is made on the basis of history followed by spirometry and laryngeal examination. Patients present with a constellation of symptoms, including difficulty breathing, a sensation of a foreign body or lump in their throat, a dry, nonproductive cough, and possibly chest tightness. These symptoms can manifest at rest, after talking, or

after physical exertion. Often the symptoms are exacerbated as the patient increases the intensity of the precipitating behavior. The disease is commonly misdiagnosed as asthma; however, the symptoms are refractory to standard management protocols. In patients with PVFMD, spirometry performed during an episode may reveal flattening of the inspiratory limb of the flow-volume curve, indicative of a variable extrathoracic obstruction¹⁵⁴⁻¹⁵⁶ (see Fig. 25-8, right panel). Laryngoscopy, considered by some to be the gold standard for diagnosis,^{154,157,158} may reveal paradoxical closure of the vocal folds during inspiration. Typically, paradoxical closure is observed during active or forced inhalation through either the mouth or the nose but is considered pathognomic by some when seen at the end of a speech utterance.¹⁵⁵ Provocation testing through increased exercise challenge, odor exposure, or even methacholine challenge may increase the sensitivity of laryngoscopy in the identification of paradoxical closure. However, even with these challenges, the sensitivity of endoscopy is still only 60% in patients with symptoms.¹⁵⁹ Therefore a presumptive diagnosis and empirical treatment may be warranted in all patients with symptoms who do not respond well to medical management for asthma.

Laryngospasm, closing of the vocal folds preventing inhalation, is a physiologic protective reflex to prevent aspiration when foreign particles stimulate the vocal folds or supraglottic structures. Laryngospasm is most commonly encountered during extubation from general anesthesia. It is managed with positive-pressure ventilation and small doses of paralytic agents to weaken vocal fold closure. Severe episodes are complicated by postobstructive pulmonary edema, which can require relatively prolonged management in the intensive care unit. In the absence of a known stimulus, recurrent episodes of laryngospasm can develop in patients with progressive neurologic disease^{160,161} or can be associated with severe forms of PVFMD. These often lead to recurrent trips to the emergency department and can be misdiagnosed as bilateral vocal fold paralysis.

In patients with recurrent episodic laryngospasm, complete neurologic examination should be undertaken to rule out a neurologic disorder. In the absence of neurologic disease, laryngospasm will often respond to the same management strategies that can be used for patients with PVFMD.

Etiology

The etiology of PVFMD is unclear. Considered by some to be a psychologic disturbance of young women, PVFMD is associated with asthma and GERD.¹⁶² High levels of stress, chronic postnasal drip, and environmental exposure to inhaled or aspirated irritants, allergies, or GERD may lead to laryngeal hyperresponsiveness, which in turn triggers paradoxical laryngeal closure. In one study,¹⁶² when patients with PVFMD were compared with normative data on the Minnesota Multiphasic Personality Inventory, 40% of the patients with PVFMD demonstrated elevation on the hypochondriasis and hysteria scales and minor elevation on the depression scale in a pattern consistent with conversion disorder. An additional 29% of these patients had significant differences in these scales but did not fit the classic conversion disorder pattern, whereas only 24% of patients

had scores suggestive of no psychopathologic conditions. Interestingly, patients with a history of asthma or GERD also scored significantly higher on the hypochondriasis scale than patients without those disorders.

The association of PVFMD with asthma, GERD, and environmental exposure to irritants raises the possibility of an organic cause in a percentage of patients with the disease. Some authors have suggested that when an organic cause is suspected, then the term *irritable larynx* should be used to describe the disorder.¹⁵⁶ In one study of patients with asthma, 19% had coexistent PVFMD, whereas only 5% of asymptomatic control subjects had any evidence of paradoxical vocal fold closure.¹⁶³

Treatment

The first step in the treatment of PVFMD is recognition of the disease. The clinical presentation is often confusing because patients may have coexistent asthma or GERD and are often resistant to the idea that behavioral change could result in any significant reduction in their symptom severity. One study estimated that the association with asthma and GERD is as high as 65% and 51%, respectively.¹⁵⁷ This association along with patients' desires to use medication to treat their problems usually leads to attempted medical trials for asthma management and therapy for GERD. With these strategies the symptoms may be reduced modestly, but the acute attacks of intermittent dyspnea, cough, and chest tightness can still be difficult to control. Therefore referral to a specialist able to perform nonsedated pharyngeal and laryngeal endoscopy is required. If the true coexistence of asthma is questionable because there is little if any response to bronchodilator therapy, then repeat pulmonary function testing before and after bronchodilator therapy and possibly with methacholine challenge is indicated. If the test results are positive, then the management of the reactive airway disease should be maximized. If the test results are negative, then all medical therapy should be stopped because the asthma medications may be exacerbating the disease by irritating the laryngeal mucosa, increasing patient anxiety, or increasing the risk for gastroesophageal reflux. If symptoms lead to a suspicion that GERD or laryngopharyngeal reflux disease is a contributing factor, then it is reasonable to treat the patient with dietary modifications and PPI therapy. Dietary modifications include avoidance of foods known to cause reflux, small meals, and avoiding reclining after eating. Therapy with PPIs should be initiated on a twice-daily basis 1 hour before the first and last meal of the day. Reflux that reaches the hypopharynx most frequently happens after meals. Therefore PPIs should be given before the meal so that a serum level can be achieved before the stimulation of acid production by the ingested food. If symptoms have not improved by 2 to 3 months after the initiation of therapy, then it is reasonable to assume that acid reflux is not playing a significant role in the pathogenesis of the patient's disease, and PPI therapy can be terminated.

Following careful history and endoscopy to rule out other causes of airway obstruction, the treatment of acute episodes of PVFMD includes reassurance, breathing instruction, and possibly the use of helium and oxygen mixture ("heliox").^{164,165} Often acute exacerbations will precipitate visits to an emergency department. The patient presents

with dyspnea, a rapid respiratory rate, and stridor. Rather than immobile vocal folds or an obstructing mass lesion, endoscopy usually reveals that the vocal folds are held in a paramedian position through inspiration and expiration. If patients are asked to cough or clear their throat, the vocal folds will usually abduct. Vocal fold abduction can be further stimulated by reassuring the patient and attempting to provide a calm, relaxed environment. Inhaling through the nose and exhaling through the nose or pursed lips (metered breathing) may also be beneficial. Alternatively the patient can be asked to breathe through a straw. Placing a restriction in the airway before the laryngeal inlet, both with the nose and lips or a straw, facilitates the patient's ability to control his or her breath and promotes laryngeal relaxation with appropriate laryngeal activity. Respiratory control or metered breathing reduces the laryngeal hypersensitivity by reducing either the respiratory rate or breath volume or both. This type of respiratory retraining is the key to chronic management of patients with PVFMD.^{166,167}

Difficulties in establishing diagnostic criteria for PVFMD are even greater than for asthma. With asthma, objective pulmonary function measures can document reversible airflow obstruction, or methacholine bronchoprovocation can demonstrate bronchial hyperreactivity. Patients with PVFMD may show flattening of the inspiratory limb of the flow-volume curve as is seen in patients with variable extra-thoracic airway obstruction, but these changes can be mimicked by submaximal inspiratory effort. Therefore there are truly no objective measures of the disease, and establishing objective diagnostic criteria is not possible. Treatment then may involve placebo effects from medications for other disorders such as GERD or asthma or active respiratory retraining to engage the patient in regaining control of his or her breathing. This respiratory training uses techniques to reduce the rate and or volume of the breath and to engage the patient in a conscious effort to control his or her breathing. Due to the difficulty in establishing diagnostic criteria, there have been few randomized controlled trials of respiratory retraining in patients with PVFMD. Limited evidence from case series has shown a reduction in the severity of patient symptoms and improvements in quality of life, which can be maintained through periodic long-term follow-up.¹⁶⁸

VOCAL FOLD PARALYSIS

Unilateral

Unilateral vocal fold paralysis rarely produces symptoms of airway obstruction. Although changes in pulmonary function can be measured during both quiet and active breathing, these are rarely clinically significant.¹⁶⁹ The proposed mechanism for potential airway obstruction when it is present is either (1) the action of inspiratory airflow producing a Bernoulli effect on the flaccid vocal fold or (2) inappropriate reinnervation of the paralyzed vocal fold with active signals for adduction during inspiration (e.g., synkinesis).¹⁷⁰ The findings can be corrected through surgery to stabilize the flaccid vocal fold complex, botulinum toxin injections to reduce the effects of the inappropriate reinnervation, or surgery to reduce the nerve supply to the synkinetic vocal fold.¹⁷¹

Bilateral

Bilateral vocal fold paralysis most commonly develops secondary to surgery in the anterior compartment of the neck for thyroid disease.¹⁷² The recurrent laryngeal nerves are either crushed or cut during the intervention, and vocal fold abduction for inspiration and adduction for phonation are lost. Immediately after the onset of the injury, patients are often able to tolerate the loss of vocal fold abduction, because the vocal folds are flaccid and immobile in a lateral position. The voice is weak and breathy. However, the recurrent laryngeal nerve contains all axons for abduction and adduction in a single fascicle. As axons regrow, the vocal fold muscles regain tone without active adduction or abduction. Because of the increased mass of the adductor muscles compared to the abductor muscle, the vocal folds adopt a more medial position. Vocal fold tone recovers in the majority of patients who suffer an injury to the recurrent laryngeal nerve.¹⁷³ This process of neural regeneration takes 3 to 9 months and leads to slowly progressive improvement in voice but progressive airway compromise. Patients adapt to this progressive airway compromise by decreasing their level of activity. The majority of patients can be managed without a tracheotomy.

A small percentage of patients develop bilateral vocal fold paralysis secondary to a Chiari malformation with increased intracranial pressure and compression of cranial nerve X in the foramen magnum by the base of the brain as it herniates through the foramen. This condition can be extremely difficult to diagnosis. Finally, a small percentage of patients will have an idiopathic etiology. In these instances the paralysis can develop bilaterally simultaneously or unilaterally separated by years.¹⁷⁴

Patient with bilateral vocal fold paralysis typically complain of minimal voice changes and note marked dyspnea on exertion. Careful history usually reveals the cause as prior surgical intervention,¹⁷² and general examination reveals prolongation of inspiration with mild to moderate inspiratory stridor. Endoscopic examination reveals bilateral vocal fold immobility with possible elongation of the vocal folds on inhalation.¹⁷² Pulmonary function testing demonstrates a classic pattern of variable extrathoracic obstruction with flattening of the inspiratory limb of the flow-volume curve and little change in the expiratory limb (see Fig. 25-8, right panel). When maximal inspiratory flow falls below 1.5 L/sec, most patients are markedly symptomatic, and intervention is warranted. If inspiratory flow is maintained around 2 L/sec, most patients can perform modest activity such as climbing one flight of stairs or walking on level surfaces.

The treatment of bilateral vocal fold paralysis is directed at static enlargement of the airway. This can be accomplished through tracheotomy. If patients choose this option, then consideration should be given to the creation of a skin-lined tracheostomy tract. This will reduce the risk for granulation tissue growth at the stoma, provide a safe stable stoma for patients to manage by themselves on a chronic basis, and allow patients to use an appliance that will hold a one-way valve so that digital occlusion is not required for phonation.¹⁷⁵ Bilateral vocal fold paralysis can also be treated by injecting botulinum toxin into the muscles of adduction. This reduces the adductor force and allows

improved function of the abductor muscles. Voice is fairly well preserved because the patient can usually override some of the effects of the botulinum toxin. The disadvantage of this treatment option is that the patient will require repeat injections.¹⁷⁶ Cordotomy or partial arytenoidectomy are also surgical options for treatment designed to remove the posterior portion of the vocal fold or a portion of the arytenoid cartilage, respectively. This enlarges the cartilaginous portion of the laryngeal airway by 1 to 2 mm without interfering too greatly with the anterior vibratory function of the vocal folds. However, because the posterior portion of the airway is enlarged on a static basis, air will leak out during phonation, and the voice will be reduced in volume as well as breathy in quality. This is referred to as “the great compromise” because the larger the airway for breathing and activity tolerance, then the worse the voice. The patient and surgeon must decide on a balance.¹⁷⁷ Additionally, one or both of the vocal folds can be sutured in a lateral position through a myriad of different techniques referred to as “suture lateralization.” Some of these techniques are potentially reversible and can be used in patients in whom recovery of function is possible, to improve their airway during this period.¹⁷⁸ Finally, experimental surgical strategies for management with electrical stimulation of the abductor muscles to open the glottis are being conducted. Initial results indicate that abduction for respiration can be achieved without compromise of vocal fold closure for voice production.

GLOTTIC STENOSIS

Scarring of the larynx, usually in the posterior portion, referred to as *posterior glottis stenosis* (PGS), most commonly develops secondary to prolonged intubation for mechanical ventilation. In fact, when patients present with bilateral vocal fold immobility after prolonged intubation, then 95% of the time the immobility is secondary to scar formation in and around the cricoarytenoid joints.¹⁷² This is a decidedly different process from bilateral vocal fold paralysis, but clinically and endoscopically it can be difficult to distinguish because visual inspection reveals the vocal folds to be immobile in the paramedian position in most patients. Helpful clinical clues to diagnosis are the events and timing around the onset of symptoms. The most common event associated with onset is prolonged intubation. As the endotracheal tube rubs against the mucosa of the posterior larynx, the mucosa is eroded and inflammation develops. Reflux may play a role in adding to inflammation or mucosal erosion.¹⁷⁹ Secondary infection of the mucosal ulceration may also play a role in adding to inflammation. After the endotracheal tube is removed, the mucosa heals by secondary intention over a 6-week period. Thus the patient notices deterioration of respiration more rapidly after a mucosal injury than after a neurologic injury; following a neurologic injury, the difficulty with respiration develops over a 3- to 6-month period as the nerve recovers partial tone.

Examination also reveals subtle differences in patients with PGS from those with bilateral vocal fold paralysis. First, patients with PGS usually have a normal voice because vocal fold adduction is maintained. On endoscopic examination there are subtle differences in the appearance of the vocal fold motion. Because the reduction in vocal fold

abduction and adduction is mechanical, the physical activity that remains is usually appropriate with abduction and adduction being well timed with inspiration and voicing. There is no evidence of spastic or synkinetic activity in patients with PGS as there may be in patients with bilateral vocal fold paralysis. Careful endoscopic evaluation usually reveals scar tissue over and around the cricoarytenoid joint. This can be subtle, with a relatively normal appearance and only slight reduction in the normal size and shape of the posterior portion of the larynx, or obvious, with overt scar tissue built up in the posterior portion of the glottis.¹⁸⁰ Finally, pulmonary function testing usually reveals a fixed extrathoracic pattern with flattening of both the inspiratory and expiratory limbs of the flow-volume loop.

Distinguishing between PGS and bilateral vocal fold paralysis is clinically significant because treatment options and outcomes are different. Whereas both bilateral paralysis and PGS will respond to tracheotomy, PGS does not respond favorably to botulinum toxin injections because of the mechanical fixation of the joint, which does not allow the entire vocal fold to move laterally when the adductors are relaxed. Rather, the relaxed vocal fold muscle tissue is held near the midline by the fixed joint. This can then collapse into the airway during inspiration secondary to Bernoulli forces and exacerbate airway obstruction. In PGS the initial surgical treatment should be aimed at release of the scar tissue that holds the joint in the fixed position. If this is not possible due to loss or remodeling of the cartilaginous joint structure, then portions of the cartilage or vocal fold can be removed. If possible, mucosal advancement flaps should be designed to cover the site of surgical excision. Because the tissue of the posterior glottis is scarred, simple incision through prior scar tissue is less likely to provide sustained significant release and more likely to heal with recurrent scar. Injudicious surgery can make the problem worse.

UPPER AERODIGESTIVE TRACT MALIGNANCIES

Malignancies of the upper aerodigestive tract are a significant cause of morbidity and mortality. Cancers of the upper aerodigestive tract constitute approximately 4% of all malignancies.¹⁸¹ *Squamous cell carcinoma* (SCC) is the predominant cancer in this region, and smoking and alcohol use have been the traditional risk factors. Surgery, radiation, and chemotherapy all play an important role in the treatment of this disease; a thorough discussion of this topic is beyond the scope of this chapter.

In the oropharynx, recent evidence has identified *human papillomavirus* (HPV) as an emerging, and now dominant, cause of malignancies. In all, 80% to 90% of newly diagnosed SCC of the tonsils or base of the tongue are HPV induced. HPV-associated oropharyngeal SCC represents a distinct clinical entity with a significantly better prognosis than non-HPV-associated oropharyngeal SCC. National Cancer Center Network guidelines now recommend HPV testing for all oropharyngeal malignancies. HPV-16 is identified as the most common HPV subtype associated with oropharyngeal malignancy.¹⁸² In SCC of the oral cavity, oral

tongue, and larynx, HPV is less commonly found; in this region, tobacco and alcohol use remain the primary risk factors. Whereas the incidence of these nonoropharyngeal SCCs is declining likely secondary to a decrease in tobacco use, the incidence of oropharyngeal carcinoma is rising, likely due to HPV.

Laryngeal cancers usually present early with voice changes. However, if the cancer arises in the supraglottic area, the subglottis, or pyriform sinus, or if the patient ignores the changes in voice and the diagnosis is otherwise delayed, then airway obstruction can be one of the presenting symptoms. In these instances the diagnosis is made through endoscopic evaluation, and the airway should be managed with endoscopic debulking of the tumor before definitive therapy is undertaken.¹⁸³

SUBGLOTTIS AND CERVICAL TRACHEA

ANATOMY, HISTOLOGY, AND PHYSIOLOGY

The subglottis is the area within the cricoid ring from the bottom of the vocal folds to the top of the first tracheal ring. The latter is the only complete ring in the airway and structurally functions to support the larynx and suspend the trachea. The subglottis is lined with a respiratory mucosa with goblet cells for mucus production and minor salivary glands as well. Mucus and saliva travel upward because of the actions of the ciliated epithelium and airflow and help humidify the airway as well as lubricate the vocal fold mucosa. In the adult human the subglottis is the narrowest portion of the airway and ranges from 15 to 18 mm in diameter. It is roughly a round or slightly oval tubular space that is narrowest just below the vocal folds and widens out at the bottom at the transition into the cervical trachea. The space extends for 1 to 2 cm in vertical dimension from the bottom of the vocal folds to the first tracheal ring. The shape of the subglottis is probably important for establishing laminar flow through the glottis. This is important for both the clearance of secretions and generating flow that will efficiently drive vocal fold vibration. Irregularities in the subglottic mucosa often lead to turbulent airflow with crust formation, which can further compromise the airway. The cervical trachea is the first four or five tracheal rings.

SUBGLOTTIC AND CERVICAL TRACHEAL STENOSIS

Pathophysiology

Because the subglottis is surrounded by a firm cartilaginous structure and the mucosa lies over the surface with only a normal submucosa for support of the epithelium, the area is particularly prone to injury from surgical manipulation or intubation, reflux disease, and autoimmune disease. Injury to the mucosa by any one of the prior processes can lead to exposure of the perichondrium, which then responds with inflammation and scar tissue formation. The scar tissue impedes airflow and mucus clearance, which can create a fixed extrathoracic airway obstruction.

The cervical trachea is most commonly injured through intervention from prolonged intubation (eFig. 49-1) or tracheotomy. Again, sloughing of mucosa from traumatic manipulation due to a movement of an endotracheal tube or repetitive deep suctioning can lead to exposure of the cartilage with inflammation and secondary collapse. Neoplasia of the minor salivary glands or squamous mucosa can also lead to obstruction.

Diagnosis

The diagnosis of subglottic or tracheal stenosis is made on the basis of patient's medical history, surgical history, and symptoms. The symptoms are primarily dyspnea on exertion and biphasic stridor. If the patient has had a prior intubation or tracheotomy, then the possibility of physical obstruction due to scarring should be considered. If a patient has known granulomatosis with polyangiitis (Wegener granulomatosis), then consideration should be given to involvement of the subglottic mucosa with inflammation, vasculitis, and granuloma formation (eFig. 49-2). In the case of idiopathic subglottic stenosis, patients are often treated for reactive airways disease without success.¹⁸⁴ These patients will benefit from early endoscopy/visualization of the subglottic region rather than weeks to months of ineffective treatment. As the name implies, there is no known cause for idiopathic subglottic stenosis. It has been presumed to be autoimmune, and the relationship with extraesophageal reflux disease is established, but the causal nature is unknown.^{179,185} Because idiopathic subglottic stenosis is found almost exclusively in women, some authors have proposed a hormonal cause.

High-resolution CT imaging (see eFigs. 49-1 and 49-2) and/or three-dimensional reconstruction of the CT images may help in diagnosis and characterization of the stenotic airway segment. But these imaging modalities are not always available, and, even if available, they may miss a short area of obstruction. Pulmonary function tests will demonstrate a characteristic plateau on the flow-volume curve (see Fig. 25-8, right panel), and the measured maximal flow can provide an estimate of the functional diameter of the flow-limiting segment (see eFig. 25-1).

The diagnosis of stenosis is confirmed with endoscopic visualization of the area. Endoscopy of the subglottis and cervical trachea for confirmation of stenosis is easily accomplished with a transnasal scope in the office setting. Lidocaine (4%) can be applied topically to the nose and can also be sprayed onto the vocal fold from above with a curved cannula or from below by injecting it percutaneously into the subglottis and asking the patient to cough. Then the flexible scope can be passed through the vocal folds and the area evaluated.

Treatment

Surgery is the primary mode of treatment of subglottic and cervical tracheal stenosis. The type of surgery, either endoscopic or open, and the use of adjuvant agents such as steroid injections or fibroblast activity inhibitors such as mitomycin C depend in part on the cause and characteristics of the stenosis. Usually treatment begins with an endoscopic approach. Rigid endoscopy allows palpation of the area to determine the nature of the scar tissue and the length of the segment of the airway that is involved. If

the segment is relatively short (less than 1.5 cm in length), occludes less than 50% of the airway diameter, and is primarily soft tissue in nature, then it will likely respond to endoscopic incision and dilation performed in a nontraumatic manner.¹⁸⁶ The incisions, which can be made with either cold steel or a laser, control the area of injury and allow the surgeon to identify the nature of the stenosis without further injury of the cartilaginous airway support. If the laser is used injudiciously, however, the surgeon can create more injury and damage to the cartilage. New-generation lasers have a very short pulse structure that results in minimal heat dissipation into the tissue beyond what is seen. Once the extent of the soft stenosis is identified, the surgeon can use that information to decide on the amount of dilation that the area will accept. The area is then dilated with a balloon to the appropriate size. Care is taken to spare islands of mucosa between the incisions to facilitate re-epithelialization before scar tissue reformation.

For very short stenotic segments or webs, any technique such as dilation alone to break up the web usually works after one or two procedures. When performed with the appropriate technique, the area of stenosis should remain dilated after the procedure during visual inspection. If the area collapses immediately after the dilation, then it is unlikely that the procedure will have lasting benefits. In addition to endoscopic incision and dilation, short and relatively discrete segments of cartilage collapse, such as may be seen at a tracheotomy site, can be resected endoscopically. Care should be exercised so that no more than 90 to 120 degrees of trachea are treated at one time. This may necessitate staging of the procedures with two or three attempts to resect the area.¹⁸⁷ The primary goal of endoscopy is to characterize the stenotic segment. If the segment is too long, involves too much cartilage, or collapses immediately after completion of the procedure, it is probably wise to proceed to open resection of the segment.

Key Points

- The upper airway contains diverse anatomic structures with a variety of functions that contribute to respiration, vocalization, smell, and taste.
- Allergic rhinitis and asthma are linked in both pathophysiologic and epidemiologic characteristics. Patients with persistent allergic rhinitis should be screened for asthma, and patients with asthma should be evaluated for allergic rhinitis.
- Although multiple medical therapies demonstrate efficacy in the treatment of allergic rhinitis, immunotherapy is the only approach known to alter the natural history of the disease.
- Chronic rhinosinusitis is an inflammatory disease of the paranasal sinuses without a single clear cause. Immune dysregulation, staphylococcal superantigens, and dysbiosis of the sinus microbiome have all been proposed as primary causes for chronic rhinosinusitis.
- Asthmatic patients demonstrate a high incidence of nasal polyps; this association is more pronounced in nonatopic asthma.

- Asthmatic patients with comorbid chronic sinusitis often experience improvement in both upper and lower airway disease after both medical and surgical treatment of chronic rhinosinusitis.
- The oral cavity structures are under voluntary control and function to regulate the intake of substances and the outflow of air for respiration and communication.
- In swallowing, the oral cavity creates a bolus of the ingested substance and presents this, in an orderly fashion, to the oropharynx and hypopharynx, where the reflexive portion of swallowing takes place. This requires structural and functional integrity and is under control of the central nervous system.
- The larynx is divided into the supraglottis, glottis, and subglottis and functions to regulate inspiratory and expiratory airflow. During swallowing, the larynx is pulled up and forward, to allow the upper esophageal sphincter to open. The bolus passes through the pyriform sinus and into the esophagus.
- During respiration the vocal folds normally open for inspiration and then close slightly during exhalation to control the rate of air egress. In *paradoxical vocal fold motion disease* (PVFMD), it is believed that these actions are reversed. The mechanism for this reversal is unknown. However, behavioral interventions designed to retrain breathing are often beneficial in patients demonstrating this finding.
- PVFMD can often be confused with asthma, but it is typically unresponsive to medical management.
- The contribution of gastroesophageal reflux disease and extraesophageal reflux disease to respiratory disorders is incompletely understood. Most of the evidence supporting an association is derived from studies

that measure patient response to empirical therapy. A few small studies using blinded randomized controls of medication and placebo do not demonstrate significant benefit of medication compared to placebo.

- Bilateral vocal fold paralysis, posterior glottic stenosis, and subglottic stenosis can often cause airway obstruction that may be misdiagnosed as asthma. Diagnosis requires suspicion based on events in the patient history and endoscopic evaluation. Treatment is usually surgical and is designed to enlarge the airway.

Clinical Features of Localized Disorders

Diagnosis of Localized Disorders

Treatment

Tracheobronchial Stents

INTRODUCTION

Previous chapters focused on the major diseases affecting primarily the intrathoracic airways. These diseases include asthma, bronchitis, cystic fibrosis, and bronchiectasis. Less common entities also primarily affect airways. Unlike the diseases discussed earlier, these entities, when diffuse, demonstrate a predilection for the peripheral airways. Their early diagnosis remains difficult, however. The large cross-sectional area of peripheral airways protects patients from symptoms of dyspnea and limits detection of flow abnormalities on functional testing until late in the disease course. Diseases affecting the peripheral airways, however, may have profound effects on lung function. Because pathologic narrowing of peripheral airways is difficult to detect, these airways may be considered a “silent zone” of the lung. Despite efforts to design tests to identify peripheral airway obstruction, none have been entirely successful. More recently, heightened recognition of the entities affecting peripheral airways and diagnostic advances have increased the frequency of diagnosis. Nevertheless, the epidemiology of disorders of the peripheral airways remains largely unknown.¹ This chapter takes into account the heightened clinical recognition and evolving efforts at classification as our understanding of these entities advances. This is most evident for *bronchiolitis obliterans* (BO). In this chapter we will first review the anatomy of the peripheral airways. Next, we will present a classification for bronchiolitis and BO that reflects a contemporary hybrid understanding of bronchiolitis based on both clinical and histologic features. Lastly, we will review focal processes involving intrathoracic airways, including a review of tracheobronchial stents.

DISORDERS WITH DIFFUSE INVOLVEMENT

ANATOMIC AND PHYSIOLOGIC FEATURES

Among other roles, the intrathoracic airways serve as a conduit between the outside environment and alveolar units. Moving distally from the trachea, bronchi transition to membranous bronchioles and ultimately to the terminal respiratory units. These transitions are defined by changes in the constellation of cell types and by architectural features. *Bronchi* are characterized by incomplete cartilaginous rings, ciliated epithelium, goblet cells, submucosal glands, and smooth muscle innervated by muscarinic output via the vagus nerve. *Bronchioles* feature sparsely ciliated simple columnar epithelium and secretory club cells (Clara) but lack cartilage, goblet cells, and glands. Bronchiolar smooth muscle is not innervated by the vagus nerve; the diameter of bronchioles ranges from 0.5 mm to 1 mm.

Because of their relatively small total cross-sectional area, bronchi are responsible for most airflow resistance in the lung. In contrast, bronchioles contribute little to total airflow resistance at high and normal lung volumes. This limited contribution is attributable to dichotomous branching that arranges vast numbers of bronchioles in parallel. This translates into a much larger total cross-sectional area for bronchioles relative to bronchi. At low lung volumes, bronchioles increase their relative contribution to total airflow resistance. As residual volume is approached, the flexible, thin-walled bronchioles, supported only by connective tissue, may collapse. Despite significant disease of the bronchioles, however, *pulmonary function test* (PFT) results

Figure 50-1 High-resolution CT scan demonstrating air trapping during expiration. A–C, Axial chest CT images performed through the upper (A), mid (B), and lower (C) lungs obtained during inspiration (see [Video 106-1](#)) in a bilateral lung transplant recipient show only minimal inhomogeneous lung opacity. Expiratory chest CT images performed through the upper (D), mid (E), and lower (F) lungs show extensive accentuation of the bilateral inhomogeneous opacity. The areas of increased attenuation represent normal collapsing lung during exhalation; the areas of relatively decreased attenuation (*arrowheads*) represent air trapping due to constrictive bronchiolitis as a result of chronic rejection.

may be normal. More commonly they may demonstrate upward concavity (“curvilinearity”) of the flow-volume curve, especially at low lung volumes, an increased slope of phase III (the alveolar plateau) of the single-breath nitrogen washout test, and air trapping. *Computed tomography* (CT) scans or magnetic resonance imaging with hyperpolarized gases, similarly, may demonstrate inhomogeneity of ventilation and air trapping ([Fig. 50-1](#) and see [Videos 106-1](#) to [106-3](#)).

DEFINING BRONCHIOLITIS

Bronchiolitis refers to a nonspecific cellular and mesenchymal reaction of the bronchioles. Developing a straightforward classification, however, is difficult. Perhaps most importantly, bronchiolitis is a catchall term subsuming several unique clinical syndromes as well as a histopathologically diverse set of lesions identifiable in many diseases. Next, there are many diseases that, in addition to causing bronchiolitis, also cause disease proximal (e.g., bronchiectasis) or distal (e.g., organizing pneumonia) to the bronchioles. As a result, some avoid defining the precise site of involvement, instead referring to peripheral airways (<2 mm diameter) as “small airways.” Lastly, clinical bronchiolitis syndromes may demonstrate more than one histologic pattern temporally and spatially. These factors conspire to preclude defining a mutually exclusive classification system. Therefore definitive diagnosis of a specific bronchiolitis entity requires clinical, diagnostic (imaging, PFTs), and frequently, histopathologic evaluation. Definitive diagnosis depends on excluding bronchial and alveolar involvement seen in alternative diagnoses. The remainder of this section will focus on diseases predominantly affecting the

bronchioles. A hybrid classification schema based on both histopathologic findings and clinical syndromes is presented in [Figure 50-2](#). The early branch points in this schema are driven by histopathologic findings, whereas later branch points are driven by clinical syndromes and exposures.

INFECTIOUS BRONCHIOLITIS

Although relatively rare in adults, infectious bronchiolitis is common in infants and young children. Community-acquired respiratory viruses are the most common cause of infectious bronchiolitis, especially respiratory syncytial virus.² Rhinovirus is the second most commonly identified virus; other viruses and bacteria may also cause disease.³⁻⁵ Infection damages bronchiolar epithelial cells. Edema, epithelial sloughing, and mucus secretion cause small airway obstruction and atelectasis. In severe cases there may be peribronchiolar lymphocytic infiltration and even mural necrosis ([Fig. 50-3A](#); see [Fig. 50-2](#), classified under the Chronic/Cellular Bronchiolitis heading). Bronchiolitis in infancy (especially non-respiratory syncytial virus) has been associated with an increased risk for subsequent wheezing and bronchial hyperreactivity.^{6,7} Although a direct link to chronic obstructive pulmonary disease has not been shown, unusual sequelae may include BO (proliferative and constrictive), bronchiolectasis, and localized emphysema.²

Typically affecting children younger than 2 years of age, bronchiolitis begins as an acute upper respiratory tract infection with rhinorrhea or nasal congestion and cough. Within days, the cough worsens and dyspnea and fever develop. Although wheezing, chest wall retractions, and cyanosis may be seen, respiratory failure is uncommon.

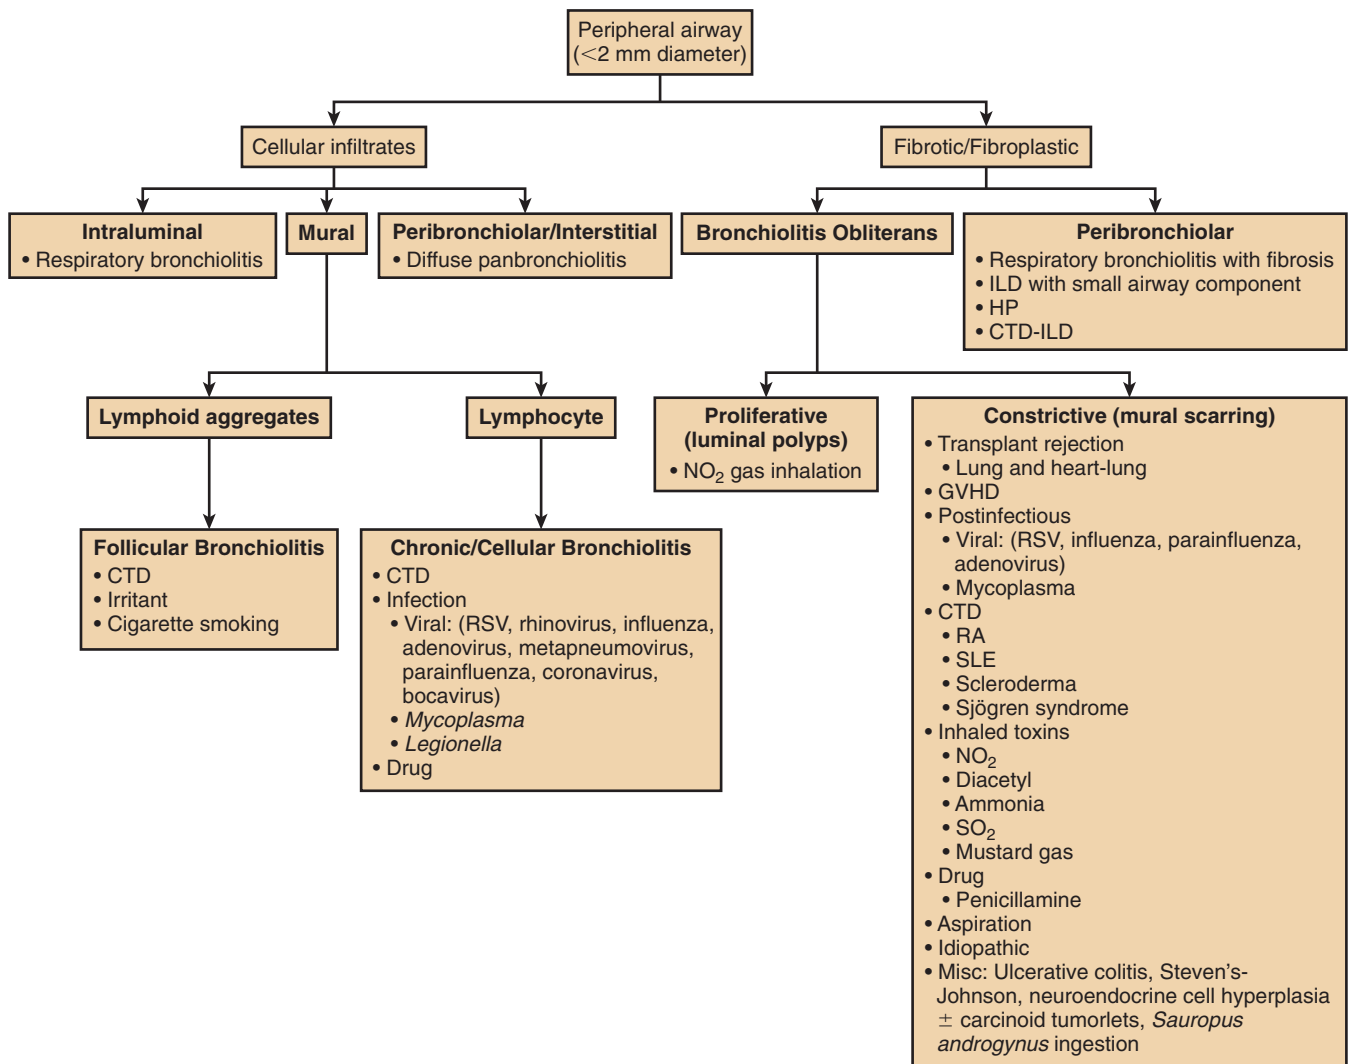

Figure 50-2 Classification schema for bronchiolitis. Traditionally bronchiolitis has been defined by clinical syndromes, as well as histopathologic lesions, making classification difficult. In this schema, early classification branch points are defined by histopathologic findings (e.g., cellular infiltrates in the small airways versus fibrosis). Later branch points are defined by specific clinical entities. CTD, connective tissue disease; GVHD, graft-versus-host disease; HP, hypersensitivity pneumonitis; ILD, interstitial lung disease; NO₂, nitrogen dioxide; RA, rheumatoid arthritis; RSV, respiratory syncytial virus; SLE, systemic lupus erythematosus; SO₂, sulfur dioxide.

Examination typically demonstrates mildly depressed oxygen saturation, tachypnea, mild chest wall retractions, expiratory wheezing, and crackles; in more severe cases, nasal flaring, grunting, pronounced chest wall retractions, prolonged expiratory phase, and cyanosis may be seen. Epithelial sloughing with bronchiolar obstruction may cause hyperinflation and gas exchange abnormalities.⁸ Generally, infectious bronchiolitis is diagnosed based on clinical signs and symptoms. When obtained, radiographs generally show hyperinflation; nodular shadows may appear in areas of focal atelectasis or pneumonia.^{5,9,10} Symptomatic treatment with nasal bulb suctioning, supplementary oxygen, and hydration is usually all that is necessary; patients usually recover within weeks. Although inhaled bronchodilators are commonly used in severe cases, their efficacy remains uncertain.¹¹⁻¹⁴ There is no proven role for corticosteroids or antibiotics, although the former are sometimes used empirically in hopes of preventing progression. Elevated cysteinyl-leukotriene levels have been reported,^{15,16}

and leukotriene modifiers have been shown to reduce respiratory symptoms and wheezing after respiratory syncytial virus bronchiolitis in some^{17,18} but not all¹⁹ studies.

BRONCHIOLITIS FROM INHALED OR INGESTED TOXINS

A generalized inflammatory response of the peripheral airways may follow inhalation of toxicants in gas, vapor, fume, or aerosol states (see Chapter 75). The location of damage is determined in part by the toxicant solubility. Highly soluble irritants such as sulfur dioxide and ammonia dissolve in the lining fluid of the upper airway, causing damage primarily there. Less soluble gases such as oxides of nitrogen are able to pass into and therefore damage the peripheral airways.^{20,21} Such exposures are a significant industrial and environmental hazard. Oxides of nitrogen, for example, may be found in silo gas (silo filler's disease), jet and missile fuel, metal pickling fumes, and certain fires.

Figure 50-3 Pathologic patterns of bronchiolitis. **A**, Infectious bronchiolitis. The bronchiolar wall shows marked acute inflammation with neutrophils and apoptotic debris extending from the sloughed epithelial surface transmurally to the adjacent alveolar spaces. **B**, Respiratory bronchiolitis. The terminal bronchiole and peribronchiolar alveolar spaces show consolidation by lightly pigmented “smoker’s” alveolar macrophages. Mild peribronchiolar fibrosis is present. **C**, Diffuse panbronchiolitis. The terminal bronchiole shows mural lymphoid inflammation, luminal inflammation and organization, and peri-bronchiolar interstitial expansion by foamy macrophages. **D**, Follicular bronchiolitis. Prominent lymphoid aggregates with well-formed germinal centers are noted adjacent to bronchioles.

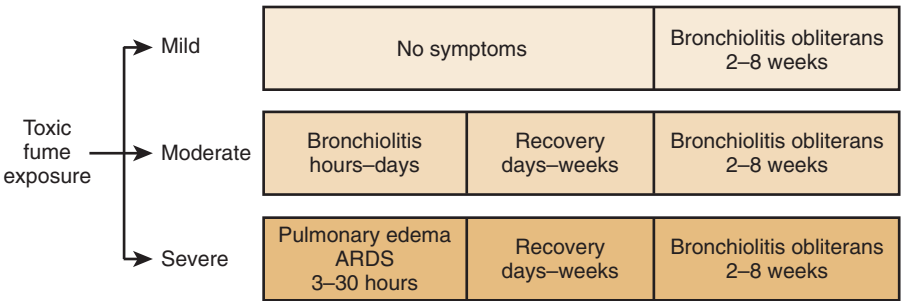

Figure 50-4 Clinical patterns of response to toxic fumes. The severity of acute bronchiolitis following inhalation of toxic fumes depends in part on the magnitude of the exposure. Most patients will recover from the acute event, although some, including some with no symptoms initially, will develop bronchiolitis obliterans (constrictive) 2 to 8 weeks after the initial insult. ARDS, acute respiratory distress syndrome.

Other fumes, such as diacetyl used in food flavoring, have been implicated in bronchiolitis as well as the development of BO (see the discussion of constrictive bronchiolitis below).^{22–24} Bronchiolitis may also result from systemic toxicant exposure as seen after administration of busulfan, gold, or penicillamine.²⁵ These causes of bronchiolitis are identified in [Figure 50-2](#) under both proliferative and constrictive BO headings.

Three clinical patterns may develop following toxicant exposure, based on several factors, including the type of toxicant, duration and intensity of exposure, and host factors ([Fig. 50-4](#)).^{20,21} Acutely, patients may develop cough, dyspnea, cyanosis, hemoptysis, hypoxemia, and loss of consciousness. These symptoms and signs may last hours to weeks before resolving. In patients exposed to higher

concentrations, pulmonary edema and acute respiratory distress syndrome may develop immediately or following a latent period of up to 30 hours. Although most patients recover, some may die from respiratory failure. Finally, some patients develop irreversible obstructive (i.e., BO) or restrictive (i.e., organizing pneumonia) abnormalities 2 to 8 weeks after exposure. This may even be seen in patients who had no initial illness; it is characterized by the gradual onset of dyspnea and nonproductive cough and may result in respiratory failure and death.^{21,26}

RESPIRATORY BRONCHIOLITIS

Respiratory bronchiolitis (RB) is a pathologic entity characterized by pigmented alveolar macrophage accumulation in

respiratory bronchioles and adjacent alveoli. Peribronchiolar inflammation or fibrosis and epithelial metaplasia extending into adjacent alveoli (lambsertosis) may be present (see Fig. 50-3B). Although nearly universally seen in cigarette smokers,²⁷ it may also be seen following mineral dust exposure.²⁸⁻³⁰ RB rarely causes symptoms or physiologic abnormalities. It is most commonly incidentally diagnosed by imaging (see Fig. 50-2, classified under the Peribronchiolar heading). In some cases, more extensive fibrosis extends into the alveolar septa. In these cases the term *RB-associated interstitial lung disease* (RB-ILD) is applied^{27,30-32} (see Chapter 63). In RB-ILD, patients present with subacute cough, dyspnea, and crackles.³³ PFTs show restriction and reduced diffusing capacity. *High-resolution CT* (HRCT) imaging shows a distinctive pattern of bronchial wall thickening, centrilobular nodules, reticulation, and diffuse or patchy ground-glass opacities.^{32,34,35} RB and RB-ILD may represent a single entity along a continuum of disease severity.^{28,33,36} Although smoking cessation leads to resolution or stabilization of disease in one third of patients,³⁷ some develop progressive ILD. Improvement with corticosteroid treatment has been described but not studied prospectively.^{27,30,31}

DIFFUSE PANBRONCHIOLITIS

Diffuse panbronchiolitis (DPB) is an obscure inflammatory disease of the respiratory bronchioles. Since its first description in 1969,³⁸ more than 1000 cases have been identified in Japan.³⁹ On histologic examination DPB is characterized by the triad of bronchiolocentric inflammation, lymphoid hyperplasia, and accumulation of interstitial foam cells (see Fig. 50-2, classified under the Peribronchiolar/Interstitial heading, and Fig. 50-3C).⁴⁰⁻⁴² Notably, similar findings are also seen in bronchiectasis, underscoring the importance of developing a diagnostic approach to bronchiolitis that considers clinical, functional, radiographic, and histopathologic findings.

Given the rarity of DPB, epidemiologic data are limited. It affects Japanese and, less commonly, other East Asian populations.⁴⁰ It is rarely diagnosed in Western countries and in persons of non-East Asian descent,^{43,44} although underrecognition may account for some of this. Clinically, DPB has a slight male predilection, and symptoms manifest in early to mid adulthood.^{39,40,45} Chronic sinusitis is exceedingly common and frequently precedes pulmonary symptoms. Before diagnosis, patients report years of nasal discharge or congestion, cough, dyspnea, and sputum production that exceeds 50 mL/day.⁴⁶ Radiographs demonstrate hyperinflation, diffuse small nodular opacities, and, in advanced disease, ring shadows and “tram track” opacities consistent with bronchiectasis. In early disease, HRCT findings may include centrilobular nodules, including “tree in bud” pattern, and air trapping on expiratory images. Mosaic perfusion is atypical. In advanced disease, bronchiolar wall thickening, dilation, and cysts are seen.^{35,47} PFTs demonstrate a progressive airflow obstruction with reduced diffusing capacity. Less commonly, a mixed obstructive-restrictive pattern may be observed.⁴⁴ Although clinical diagnostic criteria have been proposed for Japan, surgical lung biopsy is required in countries and populations in which the disease is rare.⁴⁵ If untreated, DPB leads to bronchiectasis, pulmonary hypertension, respiratory failure,

and ultimately death. Although the etiology of DPB remains obscure, both genetic and environmental factors are believed to be important.⁴⁸⁻⁵⁰ *Human leukocyte antigen* (HLA)-Bw54 is associated with a 13.3-fold increase in risk for diffuse panbronchiolitis.⁴⁹ Polymorphisms of the genes for *interleukin* (IL)-8⁵⁰ and MUC5B⁵¹ have been associated with diffuse panbronchiolitis.

Macrolides are the cornerstone of treatment.⁵²⁻⁵⁴ Although the exact mechanism of action remains undefined, anti-inflammatory and immunoregulatory properties of macrolides are likely important because their antimicrobial properties alone do not explain their benefit.⁵² Airway neutrophilia is common in DPB. Macrolides inhibit proinflammatory cytokine production, including neutrophil chemoattractants IL-8 and leukotriene B₄^{55,56}; bronchoalveolar lavage fluid levels of IL-8 and leukotriene B₄ are reduced after erythromycin treatment.⁵⁷⁻⁵⁹ Other potential mechanisms include blockage of adhesion molecules required for neutrophil trafficking,^{57,60-63} inhibition of mucin,^{64,65} and water⁶⁶ secretion into the bronchiolar lumen. Notably, 14- and 15-membered lactone ring macrolides (e.g., erythromycin, clarithromycin, azithromycin) are effective in treating DPB, whereas 16-membered lactone ring macrolides (e.g., tylosin, spiramycin) are not. For severe cases, lung transplantation has been performed, although the disease may recur in the allograft.⁶⁷

Originally DPB was a highly mortal disease. In the 1980s, 5- and 10-year survivals were approximately 62% and 33%, respectively. With macrolide therapy, increased disease diagnosis, and early, aggressive treatment of bacterial infections, 10-year survival now exceeds 90%.⁵⁴ Recurrent respiratory infections are common, and *Pseudomonas* infection, often arising late in the disease, is associated with markedly increased mortality.

FOLLICULAR BRONCHIOLITIS

Follicular bronchiolitis (lymphoid hyperplasia) is characterized by peribronchiolar hyperplastic lymphoid follicles with germinal centers (see Fig. 50-3D).^{68,69} It has been described with primary pulmonary lymphoid hyperplasia⁷⁰ or as a secondary event in collagen vascular diseases (especially rheumatoid arthritis and Sjögren syndrome), underlying congenital or acquired immunodeficiencies, bronchiectasis, or other infections^{68,71,72} (see Fig. 50-2, classified under the Lymphoid Aggregates heading). Most patients report slowly progressive exertional dyspnea, fever, recurrent pneumonia, and cough.^{68,73} PFT findings may show restrictive, obstructive, or mixed patterns. HRCT findings include small (<3 mm) centrilobular or peribronchial nodules and ground-glass opacities.⁷⁰ The natural history of this condition is unknown. Treatment is directed at the underlying disease.

DEFINING BRONCHIOLITIS OBLITERANS

BO can be stratified into “constrictive” and “proliferative” bronchiolitis. Although not absolute, this stratification is largely supported by histopathologic and clinical evidence. Unique entities featuring BO are listed in Figure 50-2; more common entities are discussed in greater detail below. Histologically, *constrictive bronchiolitis* defines a submucosal

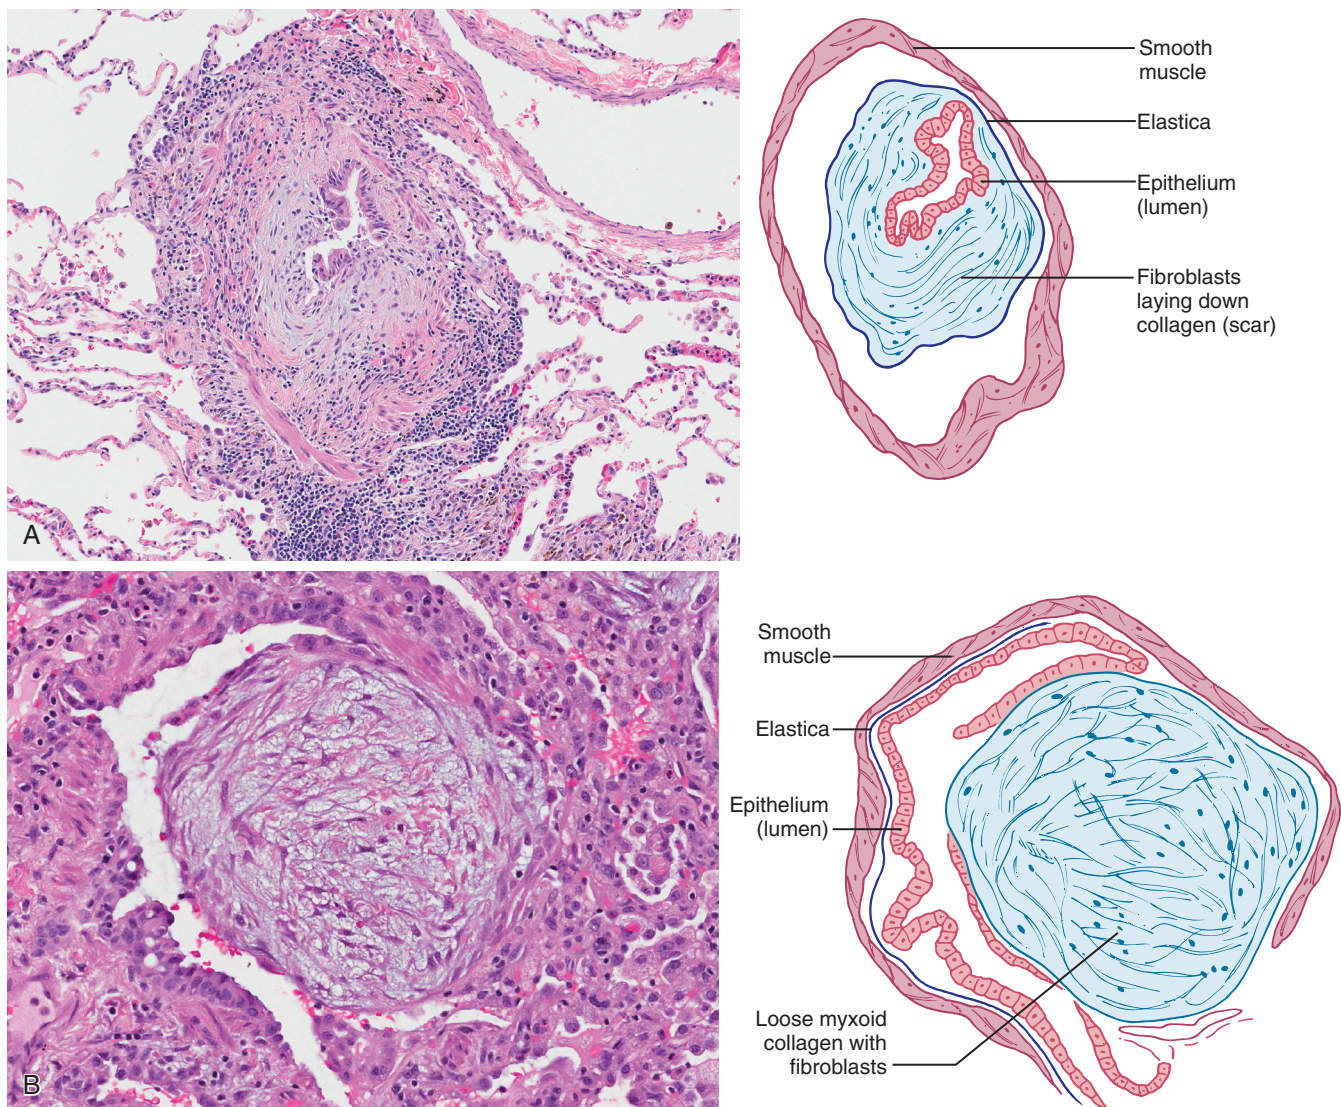

Figure 50-5 Pathologic patterns of bronchiolitis obliterans. A, Constrictive bronchiolitis. Circumferential subepithelial intramural fibrosis is present. This fibrosis separates the normally approximated epithelium and elastica. This scarring results in luminal constriction and narrowing, often with irreversible complete obstruction. **B,** Proliferative bronchiolitis. Although the diameter of the airway remains unchanged, the functional area of the lumen is reduced by a rounded intraluminal polypoid plug of granulation tissue, extending from the subepithelium and filling the airway lumen.

and peribronchiolar fibrotic process that circumferentially and externally compresses the bronchiolar lumen (Fig. 50-5A).⁷⁴ Patchy and focal in distribution, progressive fibrosis observed in constrictive bronchiolitis ultimately results in slitlike or completely obliterated bronchiolar lumens. Clinically, patients describe progressive dyspnea and nonproductive cough. Auscultation demonstrates early inspiratory crackles and occasional squeaks. PFTs demonstrate obstruction and air trapping. Radiographs may have normal findings or show hyperinflation. HRCT can demonstrate ground-glass nodules, air trapping, and, in advanced disease, bronchiectasis. Today the most common cause of constrictive bronchiolitis is chronic allograft rejection in recipients of lung transplantation.⁷⁵

Histologically, *proliferative bronchiolitis* is defined by the proliferation of intraluminal polypoid organizing fibroblastic tissue (see Fig. 50-5B).⁷⁴ Isolated proliferative bronchiolitis is rare, observed only in specific inhalational (e.g.,

nitrogen gas) exposures or localized injuries. Much more commonly, fibroblastic tissue extends from the bronchioles into adjacent alveoli. The term *organizing pneumonia* defines this organizing fibroblastic tissue in alveoli. Given the relatively common coexistence of proliferative bronchiolitis and organizing pneumonia, the term *bronchiolitis obliterans with organizing pneumonia* (BOOP) had been employed. There is little overlap, however, between the clinical entities featuring constrictive bronchiolitis and those featuring BOOP. Further, BOOP presents as a restrictive pattern on PFTs compared with the obstructive pattern seen in constrictive bronchiolitis. For these reasons, this nomenclature caused confusion. In response to this confusion, in 2002 the American Thoracic Society and European Respiratory Society jointly recommended abandoning the term BOOP in favor of *organizing pneumonia* with appropriate qualifiers. When idiopathic, for example, the term *cryptogenic organizing pneumonia* is used.⁷⁶ In rare situations, acute injury causing

proliferative bronchiolitis may progress into constrictive bronchiolitis.

Despite this evolution in nomenclature, “bronchiolitis obliterans” continues to be used imprecisely in clinical practice and in biomedical literature. The terms *BOOP*, *bronchiolitis obliterans with intraluminal polyps*, and *bronchiolitis obliterans* applied to both BO and organizing pneumonia persist. Importantly, organizing pneumonia tends to be responsive to corticosteroid treatment, whereas constrictive bronchiolitis is typically resistant. This absence of a precise nomenclature makes studies of the epidemiology, clinical features, and treatment responsiveness of “bronchiolitis obliterans” difficult to interpret. Given the substantial differences in both etiology and prognosis, we favor using the term *proliferative* or *constrictive* to more clearly define bronchiolitis obliterans.

BRONCHIOLITIS OBLITERANS AFTER LUNG TRANSPLANTATION

Over the last 3 decades, surgical and medical advancements have improved survival after transplant, resulting in increased demand for this procedure.⁷⁵ Despite these advancements, chronic lung allograft dysfunction (also known as chronic rejection) remains the major cause of morbidity and mortality in lung transplant recipients surviving beyond the first postoperative year.⁷⁵ Although new phenotypes of chronic lung allograft dysfunction have been identified,^{77,78,78a} BO is the most common form, observed in 50% of recipients by 5 years after transplant.⁷⁵ Importantly, given the patchy nature of BO, diagnosis by transbronchial biopsies is unreliable.^{79,80} In response, the International Society for Heart and Lung Transplantation devised clinical criteria for BO based on spirometric airflow obstruction “for which there is no other cause” (Table 50-1).⁸¹ Termed *bronchiolitis obliterans syndrome* (BOS), this syndrome does not require histopathologic confirmation. Most literature in human lung transplantation employs BOS as a surrogate marker for BO.

The onset of BOS is variable based on donor, recipient, and environmental factors discussed below. It presents at a median of 16 to 20 months after transplant. Patients have a median survival of 3 to 4 years after diagnosis. They report progressive dyspnea and, occasionally, dry cough. In advanced disease with bronchiectasis, the cough is productive. Spirometry demonstrates irreversible airflow obstruction with reduced diffusing capacity. CT findings in early BOS demonstrate air trapping (see Fig. 50-1 and see Videos

106-1 to 106-3). As BOS progresses, findings consistent with bronchiectasis may be seen.

BO represents the final histologic lesion likely resulting from injury to the airway epithelium and subcellular matrix via both alloimmune and nonalloimmune mechanisms.⁸² Alloimmune T-cell reactivity plays a central role in the development of BO (Fig. 50-6).⁸² Acute rejection is considered the most significant single risk factor for subsequent BOS. Although high-grade (\geq A3) rejection is a major risk factor for BOS,⁸³ even minimal (grade A1) rejection may increase the risk.⁸⁴ Additionally, frequent rejection,⁸⁵ lymphocytic bronchiolitis,^{86,87} and lymphocytic bronchitis⁸⁸ are associated with increased risk for BOS. Enhanced expression of donor *major histocompatibility complex* (MHC) antigens has been found in bronchiolar and alveolar epithelium of lung transplant recipients with BOS.⁸⁹⁻⁹¹ Recipient-derived T cells may recognize these antigens as foreign, resulting in a cascade of lymphocyte activation, proliferation, and differentiation.⁹² This concept is supported by the demonstration of activated T-cell infiltrates in allograft rejection.⁹³ A predominant CD4⁺ cell population is associated with *acute* rejection; a predominant CD8⁺ cell population is associated with BOS.⁹⁴ Animal models demonstrate that BO results from a type 1 T helper alloimmune response.⁹⁵⁻⁹⁷ The high incidence of BOS despite T-cell targeted immunosuppression, however, underscores the importance of alternate pathways to BOS.

Humoral immunity resulting in antibody-mediated rejection is increasingly recognized as a second important driver of BOS (Fig. 50-7). Donor and recipient HLA locus mismatch is associated with increased risk for BO.^{98,99} Further, donor-specific alloantibodies developing *de novo* after transplant can damage airway epithelium and endothelium and up-regulate cytokines associated with BOS.^{86,100-103} Although the link between the emergence of donor-specific antibodies and subsequent BOS is strong,^{104,104a} the diagnosis of antibody-mediated rejection remains a challenge. Defining the specific histologic features of antibody-mediated rejection is a work in progress.¹⁰⁵

BO may also develop through an autoimmune pathway (Fig. 50-8).¹⁰⁶ Through a variety of insults, injury may expose lung self-antigens, which are then presented to autoreactive T cells. This presentation induces either a cellular or humoral response ultimately resulting in BO. One such antigen is *type V collagen* (col[V]), expressed on the basement membrane of small airway epithelial cells and perivascular and peribronchiolar tissues. In murine models of acute rejection, anti-col(V) antibody deposition has been observed.¹⁰⁷ Further, col(V)-induced oral tolerance prevents both acute and chronic rejection.^{108,109} Interestingly, administration of anti-MHC class I antibodies in mice induces anti-col(V) antibody generation with resultant airway lesions resembling BO in human lung transplant recipients. Autoantibodies to the airway epithelial antigen K- α 1 tubulin increase fibrotic growth factors and other transcription factors related to BO.¹¹⁰ In lung transplant recipients, circulating autoantibodies against both col(V) and K- α 1 tubulin are strongly linked with the subsequent development of BOS.^{111,112} These responses support a link between alloimmunity and autoimmunity.

Finally, innate immunity plays a role in BOS.¹¹² Toll-like receptors on lung epithelium and antigen-presenting cells

Table 50-1 Bronchiolitis Obliterans Syndrome in Lung Transplantation Classification System

BOS 0	FEV ₁ > 90% of baseline and FEF _{25%-75%} > 75% of baseline*
BOS 0 p	FEV ₁ 81%–90% of baseline and/or FEF _{25%-75%} < 75% of baseline
BOS 1	FEV ₁ 66%–80% of baseline
BOS 2	FEV ₁ 51%–65% of baseline
BOS 3	FEV ₁ < 50% of baseline

*Baseline is the best FEV₁ and FEF_{25%-75%} obtained after transplant.

BOS, bronchiolitis obliterans syndrome; p, potential.

Adapted from Estenne M, Maurer JR, Boehler A, et al: Bronchiolitis obliterans syndrome 2001: an update of the diagnostic criteria. *J Heart Lung Transplant* 21:297–310, 2002.

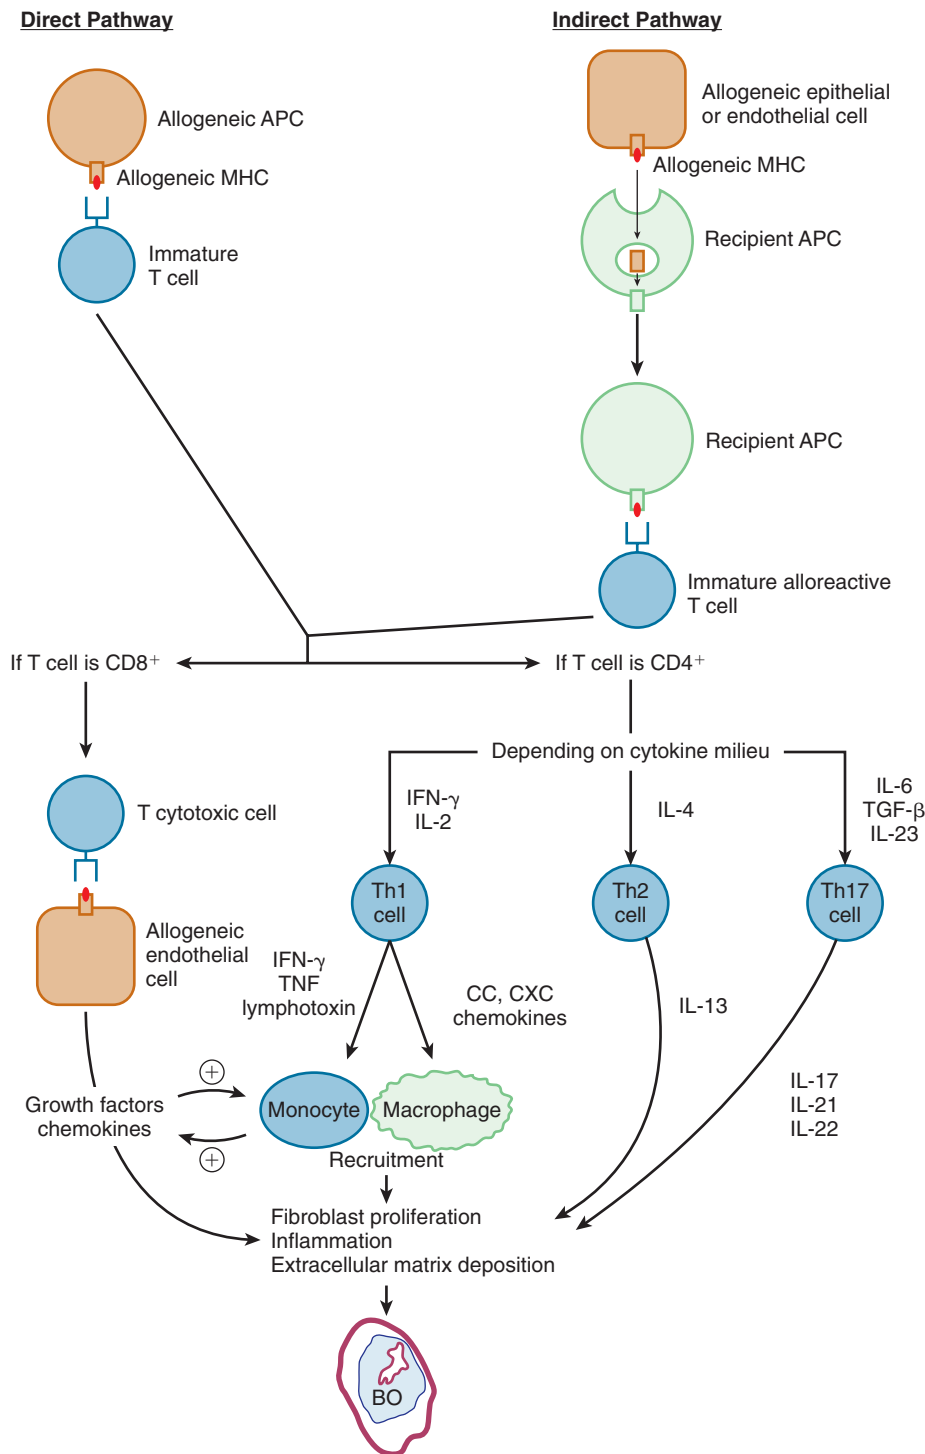

Figure 50-6 Alloimmune T-cell-mediated pathway. In the direct pathway, allogeneic peptides displayed on donor-derived antigen-presenting cells (APCs) are recognized by alloreactive recipient immature T cells. In the indirect pathway, recipient APCs engulf, process, and display allogeneic peptides to immature T cells. Immature CD8⁺ T cells differentiate into T cytotoxic cells capable of inducing growth factor and chemokine secretion. These factors (1) induce fibroblast proliferation and extracellular matrix deposition, resulting in bronchiolitis obliterans, and (2) trigger monocyte and macrophage recruitment. Macrophages trigger further growth factor/chemokine secretion as well as fibroblast proliferation. Immature CD4⁺ T cells develop into either Th1, Th2, or Th17 effector cells depending on the cytokine milieu. Each of these effector T-cell subtypes elaborates unique cytokines capable of causing bronchiolitis obliterans through different pathways. BO, bronchiolitis obliterans; CD, cluster of differentiation (e.g., CD4⁺); IFN- γ , interferon- γ ; IL, interleukin (e.g., IL-2, IL-4); MHC, major histocompatibility complex; TGF- β , transforming growth factor- β ; Th, T helper; TNF, tumor necrosis factor.

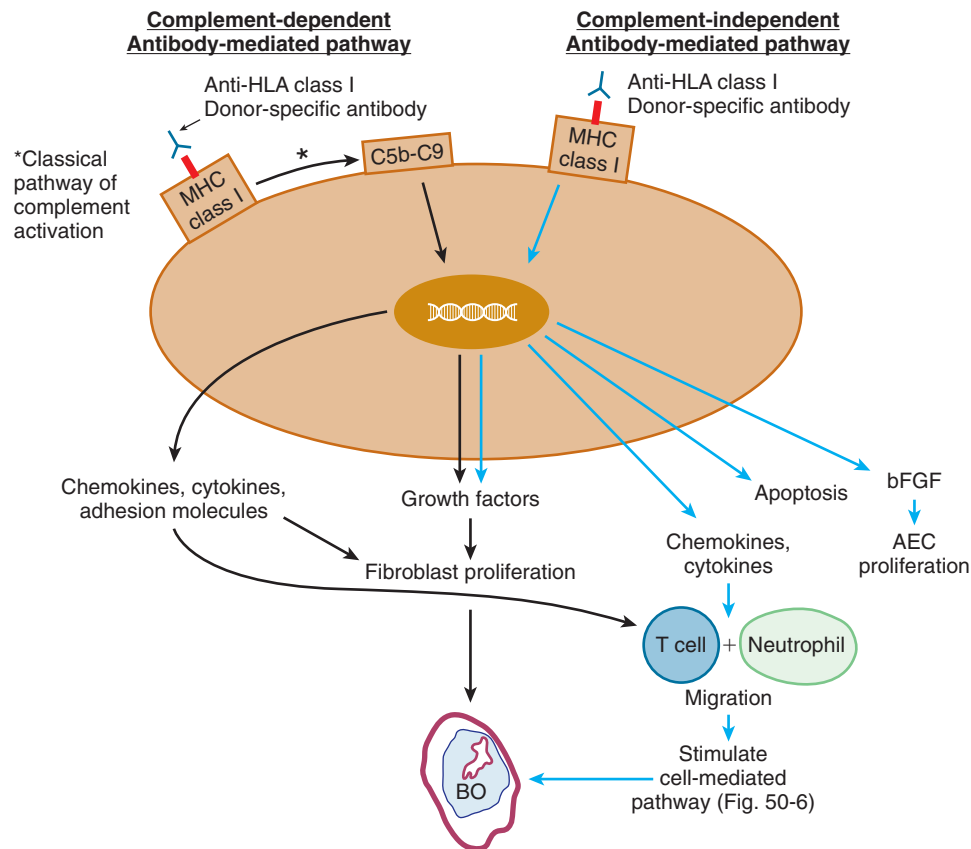

Figure 50-7 Alloimmune humoral-mediated pathway. Anti-HLA antibodies bind to donor antigens expressed on airway epithelial cells. This binding triggers a complex intracellular signaling cascade via either complement-dependent or complement-independent pathways. Complement-dependent pathways activate inflammatory genes that result in the secretion of cytokines, chemokines, costimulatory molecules (e.g., CCL2, CCL5, CXCL8, VCAM1, ICAM1), and growth factors (e.g., PDGF, HBEGF, bFGF, IGF1). These molecules can directly stimulate fibroblast proliferation, resulting in bronchiolitis obliterans (BO). In addition to growth factor secretion, complement-independent pathways stimulate chemokine and cytokine secretion (e.g., CCL2, CCL5, CXCL8), recruiting neutrophils and stimulating cell-mediated pathways (see Fig. 50-6) that also lead to BO. AEC, alveolar epithelial cell; bFGF, basic fibroblast growth factor; C5b, complement component 5b; C9, complement component 9; CCL, CC chemokine ligand; CXCL, CXC chemokine ligand; HB-EGF, heparin-binding epidermal growth factor; HLA, human leukocyte antigen; ICAM1, intercellular adhesion molecule 1; IGF1, insulin-like growth factor 1; MHC, major histocompatibility complex; PDGF, platelet-derived growth factor; VCAM1, vascular cell adhesion molecule 1.

regulate the adaptive immune response (Fig. 50-9). Loss- and gain-of-function Toll-like receptor polymorphisms are associated with differential risk for BOS.^{113,114} Although the mechanisms may be myriad, it is possible that clinical and environmental risk factors for BOS, including primary graft dysfunction,¹¹⁵⁻¹¹⁷ gastroesophageal reflux and aspiration,¹¹⁸ community-acquired viruses^{119,120} and cytomegalovirus,^{121,122} air pollution,¹²³ and fungal¹²⁴ and bacterial¹²⁵ colonization, may operate in part via the innate immune pathway. Some, for example, cytomegalovirus, may also increase the risk for BOS by increasing MHC antigen expression¹²⁶⁻¹²⁸ or through molecular mimicry.¹²⁹

BRONCHIOLITIS OBLITERANS AFTER ALLOGENEIC STEM CELL TRANSPLANTATION

BO is an uncommon complication of allogeneic stem cell transplantation, seen in 2% to 3% of patients and in 6% to 10% of those who develop chronic *graft-versus-host disease* (GVHD).¹³⁰ The histologic and clinical features of the disease are virtually identical to those seen in lung transplantation.¹³⁰ As in lung transplantation, the morbidity and mortality associated with a surgical approach to

diagnosis of BO has led investigators to avoid surgery by defining a BO *syndrome* based on clinical, radiographic, and spirometric criteria.¹³¹ This BOS is nearly always preceded or accompanied by typical findings of GVHD: mucositis, esophagitis, and/or skin rash.¹³² Four to 6 months after the onset of GVHD patients develop dyspnea and a nonproductive cough that may be severe and rapidly progressive. Physical examination may reveal scattered wheezing and frequently bibasilar crackles. Hypoxemia is common.¹³⁰ Spirometry and radiographic findings are the same as those observed in BOS in lung transplantation. Relative to lung transplantation, however, we have less understanding of the mechanisms driving BOS in stem cell transplantation. The rarity of BO following autologous stem cell transplantation and its histologic similarities to BO in lung transplantation lends support to alloimmune T-cell-mediated pathogenesis. Other mechanisms, however, have been proposed.¹³²⁻¹³⁴ The most significant risk factor for BOS is GVHD.¹³³ Other risk factors include busulfan or methotrexate¹³³ administration at the time of transplant, older age,¹³⁵ poor lung function before transplant, and respiratory viral infection within the first 100 days after transplant.¹³⁵⁻¹³⁷

Figure 50-8 Autoimmune-mediated pathway. Lung injury caused by primary graft dysfunction, community-acquired viruses, and other causes exposes small airway epithelial cell self-antigens col(V) and K- α 1 tubulin. Antigen-presenting cells (APCs) engulf, process, and present fragments of these antigens to CD4⁺ T cells. These autoantigen-reactive CD4⁺ T cells can activate either cell-mediated or humoral-mediated pathways (see Figs. 50-6 and 50-7), ultimately resulting in bronchiolitis obliterans (BO). col(V), type V collagen; ECM, extracellular matrix; IL, interleukin. (Adapted from Weber DJ, Wilkes DS: The role of autoimmunity in obliterative bronchiolitis after lung transplantation. *Am J Physiol Lung Cell Mol Physiol* 304: L307–L311, 2013.)

BRONCHIOLITIS OBLITERANS AND CONNECTIVE TISSUE DISEASES

BO may present uncommonly with connective tissue or collagen vascular diseases. Most literature linking BO and connective tissue diseases refers to cases of “BOOP.” However, constrictive BO has been reported in association with some diseases. Constrictive BO is most well characterized in rheumatoid arthritis.^{71,138} When present, it primarily affects women with long-standing rheumatoid arthritis who are smokers.^{139,140} The onset and progression of dyspnea and nonproductive cough are rapid, as is the rate of progression of airflow obstruction. Unfortunately, no consistent response to corticosteroids has been documented, and the prognosis for these patients generally is poor,¹⁴¹ although a subset of patients may have a more insidious course.¹⁴² Penicillamine, used to treat rheumatoid arthritis, has been implicated as a potential cause of BO, but confirmation of an etiologic relationship is lacking. BO has also been reported in systemic lupus erythemato-

sus,¹⁴³ in Sjögren syndrome,^{144,145} and in scleroderma, where reflux and chronic microaspiration may play an important role.^{146,147}

TREATMENT OF BRONCHIOLITIS OBLITERANS

Unfortunately, treatment of constrictive BO is often ineffective. Although there is little evidence that smooth muscle contraction plays a significant role, β -adrenergic agonists are frequently attempted to provide symptomatic relief. Literature supporting the important role of early administration of corticosteroids frequently contains mixed populations, including cases of BOOP. This is particularly true of BO after exposure to toxic fumes.^{20,148,149} Nevertheless, in an individual patient, a trial of corticosteroid therapy should be considered; if a response is identified, the corticosteroid should be continued for at least 2 to 3 months, then reduced slowly, to minimize the likelihood of relapse.¹⁴⁸⁻¹⁵² In some cases it may be necessary to continue low-dose or alternate-day therapy for months or years.

Figure 50-9 Innate immune-mediated pathway operates via Toll-like receptor (TLR)-triggered signaling pathways.

These pathways ultimately result in activation of innate immunity genes involved in inflammation and adaptive immune response activation. Numerous infectious and inflammatory events release pathogen-associated molecular patterns (PAMPs) and damage- (or danger-) associated molecular patterns (DAMPs). TLRs recognize PAMPs and DAMPs and trigger complex intracellular signal transduction via the adaptor protein MyD88 pathway or through MyD88 independent pathways. These pathways result in transcription factor activation, including NF- κ B, AP-1, and IRF-3. Transcription factors activate numerous genes involved in the innate immune response, resulting in secretion of cytokines, chemokines, and other costimulatory molecules. These molecules stimulate the adaptive immune response and directly stimulate fibroblast proliferation and extracellular matrix deposition, ultimately resulting in bronchiolitis obliterans (BO). AP1, activator protein-1; CMV, cytomegalovirus; ECM, extracellular matrix; IKK, I κ B kinase complex; IKK ϵ , inducible I κ B kinase- ϵ ; IRAP, interleukin-1 receptor antagonist protein; IRAK1, interleukin-1 receptor (IL-1R)-associated kinase; IRF-3, interferon regulatory transcription factor 3; MAPK, mitogen-activated protein kinase; MyD88, myeloid differentiation factor 88; NF κ B, nuclear factor- κ light chain enhancer of activated B cells; TBK1, TANK-binding kinase 1; TRAF6, tumor necrosis factor receptor-associated factor 6; TRAM, TRIF-related adaptor molecule; TRIF, TIR domain-containing adaptor protein inducing IFN- β .

Treatment of established BOS after lung transplantation remains disappointingly ineffective.^{152a} Augmentation or changing immunosuppression has been tried with variable response.⁸² Thrice-weekly azithromycin does improve lung function in patients with a subset of BOS demonstrating neutrophilia on BAL.^{153-155,155a} Statins may be associated with decreased rejection and BOS, perhaps by inhibiting expression of MHC class II molecules or by a variety of other antiinflammatory and immunomodulatory effects.¹⁵⁶ Uncommonly used, extracorporeal photophoresis may decrease the rate of decline in FEV₁ in established BOS.¹⁵⁷ Limited data and marginal efficacy in conjunction with the burden of delivering this intensive treatment have tempered enthusiasm for this potential therapy. For severe BOS, retransplant is the only definitive treatment and may be an option for some. The rates of recurrent BOS after a second transplant are similar to those of first transplant.^{158,159}

The most effective strategy for BOS therapy in lung transplant is primary prevention. Substantial attention is paid to identifying and treating patient-specific risk factors for BOS. Examples include surveillance bronchoscopy for acute rejection,¹⁶⁰ cytomegalovirus-specific antiviral prophylaxis,¹⁶¹ reducing aspiration through lifestyle modifications and gastric fundoplication,^{162,163} and treatment of certain community-acquired respiratory viral infections.¹⁶⁴⁻¹⁶⁶

As in lung transplant recipients, the response to BOS therapy in stem cell transplant patients is poor. Bronchodilators and corticosteroids do not generally improve airflow, and the use of immunosuppressive agents to treat chronic GVHD, although occasionally effective,^{167,168} has not consistently changed the course of BO.¹⁴¹ Macrolide antibiotics are sometimes used empirically, but there is little evidence to support this practice.^{169,170} Prophylaxis against GVHD and viral infection may reduce the risk for subsequent BOS.

BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia (BPD) is a respiratory complication of premature birth. Since the first description of BPD in 1967,¹⁷¹ the management of prematurity has evolved, including the use of antenatal glucocorticoids, perinatal surfactant, and modified mechanical ventilation. This evolution has resulted in different clinical and histopathologic entities termed “old” and “new” BPD. Old BPD was identified in newborn babies with infant respiratory distress syndrome following prolonged treatment with high concentrations of inspired oxygen and positive pressure ventilation.¹⁷¹ Characteristic histologic features include unusual abnormalities of the bronchioles, including marked metaplasia, obliteration, and cystic changes.¹⁷² The entity also has been described in adults after adult respiratory distress syndrome¹⁷³ and may be more frequent than is currently recognized. The pathologic process includes significant fibrosis of alveolar septa and resembles the honeycombing seen in other fibrotic interstitial lung diseases.^{174,175}

Contemporary management of premature infancy has improved survival of increasingly immature infants, who may experience “new” BPD.^{176,177} New BPD is milder clinically and probably reflects developmental arrest in an immature lung rather than barotrauma and oxygen toxicity.^{177,178} Histopathologic examination reveals enlarged air spaces with simplified alveolar and alveolar-capillary development. Unlike in the original disease, airway abnormalities are uncommon.¹⁷⁷

LOCALIZED DISORDERS

Many of the specific causes of localized abnormalities of bronchi also underlie abnormalities of the upper airway. Examples are neoplasms, extrinsic compression, granulomatous disease, malacic lesions, and trauma. However, the manifestations, diagnosis, and therapy of localized bronchial disorders are substantially different from similar disorders in the larynx or trachea.

NEOPLASMS

Because lung cancers are common, any endobronchial mass must be evaluated carefully for possible malignancy. All histopathologic types of primary lung cancer may protrude into a bronchus and narrow or occlude it. Malignant endobronchial tumors often have an irregular, rather than smooth, surface on bronchoscopic examination. Primary malignant tumors of the lung are described in detail in Chapters 53 and 54.

Of patients with extrapulmonary malignancies metastatic to the lung, approximately 5% have predominantly endobronchial metastases.¹⁷⁹ The most common primary malignancies are renal cell, colonic, rectal, cervical, and breast carcinomas and malignant melanomas.¹⁸⁰ In most instances the manifestations of the primary tumor are apparent before the endobronchial metastasis is discovered.¹⁷⁹ Metastatic malignancies of the lung are discussed in detail in Chapter 55.

In patients with lymphomas or leukemia, malignant infiltrations of the bronchial mucosa are rare. In Hodgkin

disease or non-Hodgkin lymphoma, the endobronchial malignant cells may originate in bronchus-associated lymphoid tissue, may invade the bronchial mucosa by direct extension from hilar or peribronchial lymph nodes, or may seed the bronchial mucosa via lymphatic or blood vessels.¹⁸¹ Leukemic infiltration of bronchial mucosa is a rare late manifestation of chronic lymphocytic leukemia.¹⁸²

The lung is involved in one third to one half of patients with *acquired immunodeficiency syndrome* (AIDS) and Kaposi sarcoma (see Chapter 90). Endobronchial lesions are seen frequently, but they rarely cause airway obstruction or hemoptysis. The lesions are usually multiple, bright red or violaceous, and flat when visualized through the bronchoscope. On CT scans, Kaposi sarcoma may appear as irregular and ill-defined, sometimes flame-shaped, nodules, with peribronchovascular interstitial thickening beginning in the perihilar region and extending toward the periphery. The diagnosis of endobronchial Kaposi sarcoma is established when a patient with AIDS has widespread extrapulmonary Kaposi sarcoma and characteristic-appearing endobronchial lesions. Biopsy of the endobronchial lesions is seldom necessary for diagnosis and may be hazardous because of excessive bleeding.¹⁸³

Benign lung tumors frequently originate from cells in the airways, including nerves (schwannomas, neurofibromas, neurilemmomas), smooth muscle (leiomyomas), cartilage (chondromas), blood vessels (hemangiomas), fat cells (lipomas), glands (cystadenomas, oxyphilic adenomas), and epithelium (papillomas). These tumors often narrow or obstruct bronchi. By bronchoscopic examination, the tumors often are smooth, round, and well localized. Benign tumors of the lung are described in detail in Chapter 56.

BRONCHIAL COMPRESSION

When peribronchial lymph nodes are enlarged by carcinoma, lymphoma, or granulomatous infection, they may narrow the adjacent bronchi. Although sarcoidosis frequently results in enlarged hilar and mediastinal lymph nodes, bronchial narrowing from compression by lymph nodes in sarcoidosis is rare. In infants with congenital heart defects such as tetralogy of Fallot and transposition of the great vessels with ventricular septal defect, bronchial compression by dilated pulmonary arteries is an occasional complication.

MEDIASTINAL FIBROSIS (see Chapter 54 and 84)

In patients with pulmonary histoplasmosis or tuberculosis, an interesting and rare complication is mediastinal fibrosis,¹⁸⁴⁻¹⁸⁶ also called sclerosing or fibrosing mediastinitis. In such patients, it appears that fungal or bacterial antigens from granulomatous foci in mediastinal lymph nodes stimulate fibrogenesis in surrounding tissue, perhaps because of unusual sensitivity to the antigens.¹⁸⁴ The fibrosis may result in narrowing or occlusion of vital mediastinal structures, and the structures affected depend on the specific lymph nodes involved by the original infection. Mediastinal fibrosis originating from subcarinal or hilar lymph nodes may result in occlusion of main-stem bronchi, pulmonary blood vessels, or the esophagus. Mediastinal

fibrosis originating from right paratracheal lymph nodes commonly produces obstruction of the superior vena cava and azygos veins.¹⁸⁴ CT and magnetic resonance imaging are useful for diagnosing and following this condition.¹⁸⁷ No medical intervention has been shown to be effective. Patients sometimes benefit from endovascular and/or endobronchial stenting.

BRONCHIAL ANTHRACOFIBROSIS

Bronchial stenosis or obliteration with anthracotic pigmentation in the mucosa was first described as a discrete clinical entity in 1998, in a retrospective analysis of 28 patients from Korea.¹⁸⁸ Characterized by multifocal bronchial stenosis, especially in the upper and right middle lobes, with multiple pigmented anthracotic lesions, the condition is thought to be due to prolonged exposure to biomass fuel.¹⁸⁹ There is a very strong association between bronchial anthracofibrosis and tuberculosis.¹⁹⁰ The diagnosis can be made at bronchoscopy, but bronchial anthracofibrosis is often mistakenly identified as mediastinal fibrosis or endobronchial tuberculosis.^{190a}

FOREIGN BODIES

Accidental inhalation of foreign bodies is a major cause of death in children, resulting in approximately 2000 deaths annually in the United States. The foreign bodies, which may be seeds, nuts, nails, or a variety of other objects, most frequently lodge in the right main-stem bronchus. Children with aspirated foreign bodies may present with immediate cyanosis, cough, and wheezing or with the delayed onset of pneumonia or bronchiectasis. Suspected aspiration of a foreign body is an indication for immediate bronchoscopic examination of the airways. In the presence of asphyxia, rigid bronchoscopy is appropriate. In most other situations, foreign bodies can be extracted with the flexible bronchoscope, but personnel and equipment for rigid bronchoscopy should be available (see Chapter 23).

GRANULOMATOUS INFLAMMATION

In patients with pulmonary tuberculosis, spillage of infected material into the middle and lower lobes occasionally causes localized endobronchial infection. Endobronchial tuberculosis may present with hemoptysis, bronchorrhea, or localized bronchial obstruction, causing lobar collapse and persistent postobstructive pneumonitis. These findings may develop during active pulmonary infection by tuberculosis or many years after its treatment. The diagnosis is established most readily by fiberoptic bronchoscopy.¹⁹¹ The typical finding is the presence of localized endobronchial gelatinous granulation tissue. The mucosa may be nodular, red, and ulcerated, and often the diagnosis of bronchogenic neoplasm is suggested until pathologic examination of biopsy material has been carried out.

In patients with pulmonary sarcoidosis, localized endobronchial granulomatous inflammation rarely may lead to stenosis of bronchi.¹⁹² PFT results often show airway obstruction, but the common causes of the obstruction are the structural distortion of bronchi and bronchioles that accompanies pulmonary fibrosis,¹⁹³ nonspecific bronchial

hyperreactivity,¹⁹⁴ or laryngeal sarcoidosis.¹⁹⁵ Only rarely is bronchostenosis present.

Bronchocentric granulomatosis is an uncommon inflammatory lesion defined morphologically by the presence of necrotizing granulomas surrounding bronchi.¹⁹⁶ The entity develops most commonly in asthmatic patients with allergic bronchopulmonary aspergillosis, and considerable evidence suggests that the granulomatous bronchitis is an immunologic response to endobronchial fungi. Cases have also been reported in association with other infections (mycobacterial or fungal) and with rheumatologic disease, and a significant proportion are idiopathic. The bronchi may be narrowed or obliterated because of the inflammatory reaction itself or because of associated mucoid impaction.¹⁹⁶

BRONCHOLITHIASIS

Broncholithiasis is defined as the presence of a calcified fragment of tissue within a bronchus.¹⁹⁷ Any disorder that leads to calcification of lung tissue or of lymph nodes may result in broncholithiasis. This most often happens when hilar or peribronchial lymph nodes become calcified as a result of granulomatous infections such as histoplasmosis or tuberculosis, or less commonly from actinomycosis, coccidioidomycosis, cryptococcosis, or silicosis.^{197,197a} Necrotizing pneumonias and bronchiectasis may lead to calcification of bronchial cartilage, which can fragment to produce broncholiths. Occasionally, retained foreign bodies may become calcified. Broncholithiasis manifests clinically when calcified stones erode or break loose into the airways (see later). These stones are composed of 85% to 90% calcium phosphate and 10% to 15% calcium carbonate and thus closely resemble the composition of bone.

AMYLOIDOSIS

Amyloidosis is defined on the basis of the extracellular deposition of the fibrous protein amyloid. In both the primary and secondary forms of the disease, amyloid can deposit endobronchially, producing hoarseness, wheezing, or stridor, or incidental findings at the time of bronchoscopy.¹⁹⁸ The airway mucosa demonstrates irregular thickening with waxy firm deposits that may appear white, gray, or yellow. As many as 30% of patients with primary amyloidosis are symptomatic. Pulmonary involvement is usually associated with amyloid of the light chain variety.¹⁹⁹ The definitive diagnosis of endobronchial amyloidosis requires biopsy and demonstration of amyloid deposits, as defined by their green birefringence when viewed with polarized light after staining with Congo red.¹⁹⁸ A recent report suggests that confocal endomicroscopy may identify early-stage tracheobronchial amyloid.²⁰⁰ Endobronchial amyloid has been treated successfully with *neodymium:yttrium-aluminum-garnet* (Nd:YAG) laser therapy.²⁰¹

TRACHEOMALACIA AND BRONCHOMALACIA

Softening of the tracheal or bronchial walls may contribute to narrowing and collapse of the airways during exhalation. This can develop as a result of inherited disease (e.g., congenital polychondritis) or may be acquired as a result of

trauma, infection, chronic inflammation (e.g., relapsing polychondritis), or emphysema. Less commonly, bronchomalacia may be found in infants because of inadequate development of bronchial cartilage. These infants generally present with dyspnea, atelectasis, or recurrent pneumonias. CT scans, maximal flow-volume curves, and direct visualization by bronchoscopy are all helpful in confirming the diagnosis. Pharmacologic treatment is rarely effective, and stents or surgical intervention may be necessary for patients who are very symptomatic.

TRAUMATIC INJURY (see Chapter 76)

Tears or complete ruptures of main-stem bronchi or the bronchus intermedius are occasional complications of blunt trauma to the chest. The diagnosis should be suspected in any posttraumatic patient with new onset of cough, respiratory distress, subcutaneous and mediastinal emphysema, or pneumothorax. The associated presence of hemoptysis or hemothorax indicates bronchial vascular damage. Occasionally the development of manifestations of bronchial tears may be delayed days or weeks after the traumatic injury.

CLINICAL FEATURES OF LOCALIZED DISORDERS

Patients with localized endobronchial lesions generally present with symptomatic, physical, or radiographic manifestations of the lesion itself or of underlying conditions (e.g., malignancy, infection, AIDS, or sarcoidosis). Only the manifestations of the lesions themselves will be described in this section.

The most common symptoms of localized endobronchial disease are cough, hemoptysis, wheeze, dyspnea, and fever and chills secondary to postobstructive pneumonia. If an endobronchial lesion only partially obstructs a bronchus, patients may show manifestations of chronic pulmonary infections, such as lung abscess (see Chapter 33) or bronchiectasis (see Chapter 48). A history of recurrent pneumonias in the same segment or lobe of the lung should prompt a careful evaluation for partial bronchial obstruction by an endobronchial lesion. Similarly, for any edentulous elderly patient with a history of a severe anaerobic pulmonary infection, endobronchial obstruction should be considered.

Symptoms of broncholithiasis include cough, hemoptysis, fever associated with purulent sputum, and expectoration of stones. Often the cough in broncholithiasis is productive of a mixture of gritty, sandy particles and purulent or bloody sputum.

The physical examination in patients with localized endobronchial lesions may reveal fever and tachypnea. When a bronchus is narrowed but not completely obstructed, examination of the chest may reveal a unilateral palpable rhonchus, a localized wheeze during a forced expiratory maneuver, or a prolonged sibilant sound that persists after the expiratory or inspiratory effort has ended, the “bagpipe sound.”²⁰² Once the obstruction is complete, there is a loss of breath sounds and tactile fremitus over the portion of the lung distal to the obstruction.

In patients with localized endobronchial disease, the chest radiograph may show no abnormality. Radiographi-

cally apparent lung collapse depends on the completeness of the obstruction and on the extent to which collateral ventilation from adjacent lung is present. In infants the pores of Kohn, the sites of collateral ventilation, are poorly developed. Hence the likelihood of complete collapse from localized bronchial disease is great in this age-group. Other findings on the plain chest radiograph include mediastinal adenopathy with or without calcification, lung abscess, bronchiectasis, or pneumonia. The presence of air bronchograms in a consolidated region of the lung suggests that the bronchus supplying that region is at least partially patent.

Middle lobe syndrome refers to chronic or recurrent radiographic evidence of collapse of the *right middle lobe* (RML). Originally it was postulated that the cause was tuberculous adenitis of lymph nodes in the RML causing bronchial compression.²⁰³ *Obstructive middle lobe syndrome* can result from extrinsic compression by inflammatory lymphadenopathy or from endobronchial tumors. However, in most patients, bronchoscopy and CT scans do not demonstrate obstruction. This *nonobstructive middle lobe syndrome* is thought to relate to the normal, relatively long length and narrow caliber of the RML bronchus or to the relatively ineffective collateral ventilation normally present in this lobe.²⁰⁴ The anatomy itself leads to poor mucus clearance from the RML and to mucus plugging of peripheral airways. The poor collateral ventilation of the RML limits reexpansion once there is atelectasis. Patients with middle lobe syndrome often report multiple episodes of recurrent RML pneumonia. In addition, bronchiectasis is found in approximately 50% of patients with middle lobe syndrome. The most common clinical features of middle lobe syndrome are recurrent infection, chronic productive cough, chest pain, or dyspnea.²⁰⁵

DIAGNOSIS OF LOCALIZED DISORDERS

In patients with only partial obstruction of a bronchus, comparing radiographs obtained at full inspiration with those obtained at full expiration may assist in establishing the diagnosis. Upon inspiration, the negative intrathoracic pressure distends the partially obstructed bronchus, and air enters the distal lung. Upon expiration, the obstruction becomes complete, and air is trapped behind it. The result is a mediastinal shift away from the affected side on expiration. CT scans may identify hyperinflation, compressing lymph nodes, or calcifications in patients with broncholithiasis, or subtle endobronchial abnormalities.²⁰⁶

The definitive procedure for diagnosing localized bronchial abnormalities is direct examination of the bronchi via fiberoptic bronchoscopy. In general, any visualized abnormality should be biopsied and the biopsied materials submitted for histologic examination as well as for culture. If the lesion is friable and bleeds easily during its examination and manipulation, rigid bronchoscopy may be required.

Routine PFT results in general do not distinguish between localized and widespread bronchial obstruction. In patients with bronchial compression or mediastinal fibrosis, skin tests for histoplasmosis or tuberculosis may be positive.¹⁸⁴ In bronchocentric granulomatosis, peripheral blood eosinophilia and serum precipitins for *Aspergillus* may be present.¹⁹⁶ Because bronchocentric granulomatosis is probably a

hypersensitivity reaction to *Aspergillus*, galactomannan levels are typically normal.²⁰⁷ In endobronchial amyloidosis, immunoelectrophoretic analysis of blood or urine shows evidence of monoclonal gammopathy in 90% of cases.²⁰⁸

TREATMENT

The appropriate therapy for localized lesions of the bronchi depends on the specific underlying cause. Treatment of bronchial obstruction is described in Chapter 23. In some patients with inoperable obstructive neoplasms of the trachea, main-stem bronchi, or bronchus intermedius, the use of the Nd:YAG laser, electrocautery, or argon plasma coagulation can provide immediate relief; the therapeutic effects of cryotherapy, brachytherapy, and photodynamic therapy are slower in onset. Bronchial obstruction from extrinsic compression or endobronchial granulomatous inflammation may be relieved by medical treatment of the underlying condition (e.g., lymphoma, tuberculosis), but irreversible fibrotic narrowing often requires surgical resection or stenting. There are reports that airway and vascular obstruction due to mediastinal fibrosis may improve with corticosteroids or with stenting, and that anthracofibrosis may improve with antituberculous treatment, but prospective trials are lacking. Foreign bodies usually can be removed with specialized wire claws or baskets inserted through a bronchoscope. When they are lodged in central airways, removal of foreign bodies is performed most effectively via a rigid bronchoscope. Broncholithiasis is often self-limited, requiring no further evaluation or treatment. However, if hemoptysis, persistent cough, atelectasis, or infection is present, bronchoscopic evaluation should be considered for stone removal. Antibiotics should be administered to treat postobstructive infections. Occasionally, surgical intervention is required to manage persistent or recurrent broncholithiasis.¹⁹⁷ In infants with bronchomalacia, effective treatment may require long-term ventilation of the lungs until normal cartilage is formed, which usually happens by 6 months to 2 years of age. Patients with suspected traumatic bronchial injury should undergo immediate endotracheal intubation and fiberoptic bronchoscopy followed by thoracotomy.

TRACHEOBRONCHIAL STENTS

Although prostheses have been used to relieve tracheal and bronchial obstruction for many years,²⁰⁹ recent technical advances have made the procedure easier and more effective.^{209a} More than 20 types of tracheobronchial stents are now available, in metal, mesh, or silicone rubber; insertion usually can be accomplished by fiberoptic bronchoscopy without general anesthesia. Stents have been used effectively to relieve airway obstruction caused by malignancy, postinflammatory stenosis, and tracheobronchomalacia, and to occlude tracheoesophageal fistulas. The success rate is greater than 80% to 90% in selected patients.²¹⁰⁻²¹² Fenestrated or mesh stents are more effective for benign lesions than for neoplasms, which tend to grow through the metal mesh. Careful patient selection, choice of the correct stent, and an experienced bronchoscopist are important determinants of success. Virtual bronchoscopy using CT is often useful in planning stent placement.

Key Points

- Because of the large cross-sectional area of the peripheral airways, symptoms and physiologic changes develop late in disease involving the peripheral airways and conditions affecting these airways, including bronchiolitis and mucus plugging, can be silent.
- Bronchiolitis obliterans syndrome after lung transplantation results from chronic graft rejection; it is the final result of several immune-mediated pathways, including cell-mediated, humoral, autoimmune, and innate.
- Bronchiolitis obliterans after bone marrow transplantation results from chronic graft-versus-host disease.
- Diffuse panbronchiolitis responds to treatment with macrolide antibiotics.
- Endotracheal and endobronchial stents are effective for treating obstruction caused by tumors, postinflammatory stenosis, and tracheobronchomalacia.

INTRODUCTION

Lung cancer is the number one cause of cancer-related death in the Western world. Lung cancer remains the leading cause of cancer mortality for both men and women in the United States.¹ Its incidence is highly correlated with cigarette smoking, and lung cancer is eventually diagnosed in about 10% of long-term smokers. Among the 10% to 15% of patients without a smoking history in whom lung cancer develops, environmental or inherited causes of lung cancer contribute to the risk. As large as the clinical challenges patients and physicians face in managing this disease, equally enormous are the challenges in detailing the complex molecular pathogenesis of lung cancer. Major progress has been made, however, and we are beginning to see this knowledge translated into the clinic. In this chapter, we summarize our understanding of how lung epithelial cell injury leads to signaling pathway activation that triggers the uncontrolled proliferation, resistance to apoptosis, metastasis, and escape from immune surveillance seen in lung cancer. Whereas all subtypes of lung cancer have historically been divided between *non-small cell lung cancer* (NSCLC) and *small cell lung cancer* (SCLC), the field is stepping away from purely histologic classification and moving into molecular classification of tumors based on better

understanding of driver genes² and the potential benefit of therapeutic strategies using targeted therapies that interfere with mechanisms of tumor growth and progression.³

The pathogenesis of lung cancer involves the accumulation of multiple molecular abnormalities over a long period of time.⁴ Alterations in gene expression can result from abnormal microRNA expression or methylation, DNA sequence changes, DNA segment amplification, deletion, or whole chromosome gains or losses. These lesions allow cells to escape the normal regulation of cell division, apoptosis, and invasion and/or alter its interaction with the host. The historical focus of much of this research has been to identify and study the role of specific genetic abnormalities in tumor cells related to chromosomal abnormalities, inactivation of specific tumor suppressor genes, the activation of specific oncogenes, and the expression of hormone receptors and growth factor production associated with the development of cancer. More recently, the contribution of stromal interactions, the induction of angiogenesis, the control of apoptosis, and epigenetic phenomena such as posttranslational modification of critical genes have been the subject of intense research. The completion of the first draft of the human genome sequence^{5,6} and the availability of high-throughput technologies (e.g., microarrays) have also prompted investigators to propose studies to discover

molecular alterations of individual tumors with incredible sensitivity and unprecedented scope. Common molecular abnormalities in both precancerous and invasive lung cancers are being integrated and hold the promise for potential utility in prevention, early detection, and therapy.

PREDISPOSITION TO LUNG CANCER

SMOKING

Tobacco use continues to be a major cause of cancer in the world. Worldwide, tobacco use causes more than 5 million deaths per year, and current trends show that tobacco use will cause more than 8 million deaths annually by 2030.⁷ Tobacco control efforts are leading to a decrease in cancer mortality in some areas of the world,⁸ but globally there are still more than 1 billion smokers.⁹ More than 85% of all lung cancers are attributable to cigarette smoking; however, lung cancer develops in only a fraction of long-term cigarette smokers, suggesting a role for variable inherited genetic susceptibility in lung tumorigenesis.

Lung cancer develops through a multistage process in a background of increasing genomic instability and inflammation.¹⁰ For example, cytogenetic alterations arise throughout the airways with monoclonal and trisomic clonal patches observed.¹¹ Patches of epithelial cells presenting with $2n + 1$ number of chromosomes develop diffusely in the airway following the distribution of cigarette smoke exposure and confirm the “field cancerization” hypothesis.¹² Elucidating the molecular determinants responsible for the development of lung cancer and identifying intermediate biomarkers associated with malignant progression remain a priority. Cigarette smoking clearly contributes to the accumulation of genetic alterations in lung cancer.^{13–15} Tobacco is rich in pulmonary carcinogens and causes many genetic changes by inducing DNA mutation.^{16,17} Tobacco-specific nitrosamines induce DNA methylation¹⁸; levels of DNA adducts such as methylated DNA can, in fact, be used as an index of human tobacco exposure. Tobacco causes methylation of tumor suppressor genes.^{19,20} Cigarette smoke has also been shown to induce demethylation of the proto-oncogene synuclein- γ in lung cancer.²¹ Therefore, cigarette smoke could lead to specific patterns of chromatin structure alterations that may promote cancer development. In the future, specific epigenetic alterations induced by cigarette smoking may be useful as biomarkers of lung cancer development. Chronic exposure to carcinogens initiates a process characterized by genetic abnormalities, phenotypic changes, and overgrowth of clones of genetically altered epithelial cells throughout the lungs.²² Genomic alterations may form a pattern referred to as a “genomic signature.” The signatures found in NSCLC may contain information about their induction by cigarette smoke²³ and may reflect the pathways to cancer development or represent the product of competitive selection of clones.^{24–27} In fact, the clinical profile (Table 51-1) and molecular profile of lung tumors arising from never-smokers are quite distinct from their smoker counterparts.²⁸

Table 51-1 Characteristics of Lung Cancer Found in Never-Smokers

Frequent <i>EGFR</i> and <i>TP53</i> mutations
Rare <i>KRAS</i> mutations

GENETIC SUSCEPTIBILITY AND FAMILIAL PREDISPOSITION

In epidemiologic studies, smoking confers an approximately 14-fold increased risk for lung cancer and, after controlling for tobacco use, a family history of lung cancer accounts for an approximately 2.5-fold increased risk. Here, we address susceptibility as it relates to genetic susceptibility and familial predisposition separately.

Genetic susceptibility may be seen with rare autosomal dominant genes that explain cases of early-onset lung cancer but more common genetic variants or polymorphisms are more likely to affect lung cancer risk. Inherited differences in DNA repair capacity in response to tobacco-mediated damage have been incriminated as underlying some of this susceptibility. When lymphocytes from lung cancer patients and age-matched controls are exposed to bleomycin, the lymphocytes from lung cancer cases develop more chromatid breaks than the control lymphocytes.²⁹ A similar assay has been developed using benzo(α)pyrene diol-epoxide, a reactive substrate that is derived by in vitro processes from benzo(α)pyrene, a major carcinogen in tobacco smoke.³⁰ These results suggest that the DNA repair capacity influences risk for lung cancer. Telomere length has also been inversely associated with lung cancer risk.³¹ Nicotinic acetylcholine receptor subunit genes may contribute to the risk of smoking as well as the risk of lung cancer. In three lung cancer genome-wide association studies, polymorphic differences in chromosome 15q25 have been associated with the risk of developing lung cancer.^{32–34} Single nucleotide polymorphisms mapped to a region of strong linkage disequilibrium within 15q25.1 contain nicotinic acetylcholine receptor subunit genes. The genetic variants were associated both with nicotine dependence as well as with certain lung cancer phenotypes, including lung cancer developing in younger patients and in patients with lower amounts of smoking; the variants were not associated with lung cancer in nonsmokers or with other smoking-related cancers like renal or bladder.³⁵ Since then, subsequent analyses have identified additional variants that influence lung cancer risk,³⁶ which will require further investigation in a larger sample size. The relative impact of the nicotinic acetylcholine receptor gene variants on the propensity to smoke or on the response to the direct carcinogenic effects of smoke is undergoing validation in large numbers of smokers and nonsmokers.

Familial risks of lung cancer provide another route for uncovering susceptibility genes. In one genome-wide linkage analysis, a genomic locus on chromosome 6q23–25 has now been associated with a familial risk of lung cancer.³⁷

To date, no tumor suppressor genes inactivated by mutation have been identified in this locus, although the frequent inactivation of multiple candidate tumor suppressor genes within chromosome 6q likely contributes to development of sporadic lung cancer.³⁸ Finally, a genome-wide association analysis was conducted to investigate associations between single nucleotide polymorphisms and the risk of lung cancer in 194 patients with familial lung cancer and 219 cancer-free control subjects.³⁹ A strong association was found between common sequence variants at 15q24-25.1 and lung cancer.⁴⁰ The risk of lung cancer was more than fivefold higher among those subjects who had both a family history of lung cancer and two copies of high-risk alleles in the 15q24-25.1 locus as compared with control subjects.³⁹ Thus, studies into sporadic and familial cancer risk may identify some of the same genetic predispositions, such as 15q24-25.1 or germline *EGFR* T790M mutations,^{41,42} and have the potential to identify novel genetic predispositions.

Mathematical models integrating clinical, physiologic, imaging, and biologic variables are now proposed for evaluating risk for lung cancer in clinical practice.⁴³⁻⁴⁷ This field has made tremendous progress, and prediction models are being proposed for implementation in selecting populations for screening and/or chemoprevention trials.

EARLY EVENTS IN LUNG TUMORIGENESIS

FIELD CANCERIZATION EFFECT

Whereas lung cancer may originate from only one or a few airway epithelial cells, it is clear that exposure of the whole airway mucosa to tobacco smoke can cause the entire bronchial tree to be at increased risk for development of lung cancer, leading to the concept of field cancerization (Fig. 51-1). Field cancerization was first proposed in the 1950s,¹² and its molecular correlates were later confirmed in the airways of human smokers.⁴⁸ Field cancerization is also demonstrated by the elevated Ki-67 labeling index in the airways of smokers at more than one site.⁴⁹ In addition, evidence has been found in a single smoker with diffuse dysplasia that a single identical point mutation of *TP53* could be found diffusely in both lungs, but not in the blood or other solid organs, suggesting that a single progenitor bronchial epithelial clone populated the bronchial mucosa. Although the risk of developing lung cancer increases with the presence of such preinvasive lesions, clearly the entire at-risk epithelium does not undergo malignant transformation, and no one has identified the molecular determinants of preinvasive lesions that may predict irreversible progression to lung cancer. Thus, if one considers the total number of bronchial epithelial cells and the proliferation rate of patches of clonal abnormalities, cancer remains a rare event.⁵⁰

The concept of field cancerization has implications for approaching diagnosis, prevention, and treatment of lung cancer. For example, diagnostic information may be contained even in the normal-appearing airway epithelium; in patients with and without lung cancer, changes in the airway field have been found to correlate with the presence

Figure 51-1 The field of injury. The field of injury could serve as means for assessing the risk of developing lung cancer, of having lung cancer, or even predicting the behavior of a tumor in the field. In this figure, the lung epithelial surface area is displayed as if it were a tennis court, known to be of roughly comparable size. The tumor (red) and associated genetic alterations (red and yellow stars) are shown as stochastic events. Investigations to understand the role of the field in disease pathogenesis can take advantage of the study of tumor samples, and adjacent bronchial biopsies, bronchial brushings, or related serum or plasma (red area surrounding the field) as well as tumor samples.

of lung cancer elsewhere in the airways or with an elevated risk for transformation.^{25,51} Similarly, prevention efforts should be directed to the entire epithelium, which can then also provide biomarkers for effective prevention. Finally, the field cancerization concept has major implications for therapy, because one should consider treating the entire field as opposed to limiting treatment efforts to preinvasive lesions that may never develop into lung cancer.^{52,53}

GENOMIC INSTABILITY

Lung cancer develops along a multistage process in a setting of increasing genomic instability. Genomic instability is universally found during accumulation of these genetic abnormalities.^{54,55} Genome instability is a fundamental characteristic of cancer initiation and progression. However, our understanding of the onset of instability, the rate of instability, and the mechanisms leading to instability is far from complete. We do know that—from initiation, to promotion, to the development of an invasive phenotype—a series of molecular changes contribute to a molecular instability that puts the airway epithelium of some smokers at greater risk for lung cancer.

Two main theories of the genomic changes underlying lung tumorigenesis have emerged: the stochastic (random) and the gene-centric (nonrandom) theories. The *stochastic theory* argues that lung cancer arises by genomic aberrations that are stochastic or random in nature.⁵⁶ Indeed, in many tumor types, there are relatively few cancer-specific mutations, whereas there can be a high degree of chromosomal aberrations.⁵⁷⁻⁵⁹ Some of these low-level aberrations have been called noise but may reflect the underlying instability. Nonclonal chromosomal alterations such as defective mitotic figures, chromosomal fragmentation, or nonrecurrent genomic alterations indicate a dynamic process leading to instability.⁵⁶ Nonclonal chromosomal alterations may provide a survival advantage, whereas clonal chromosomal alterations at a later stage of progression may confer a growth advantage.⁶⁰

In contrast, the *gene-centric theory* argues that sequential accumulation of epigenetic and genetic aberrations is important for lung cancer development.⁶¹ This gene-centric theory is particularly appealing to explain clonal alterations in genes implicated in tumor cell growth and survival that represent possible targets for the management of cancer.⁶² These alterations include single nucleotide point mutations, changes in chromosome copy number (aneuploidy),^{63,64} and specific genomic amplifications or deletions.⁶⁵⁻⁶⁷ These genetic changes are implicated in the pathogenesis of tumor development in part through the activation of oncogenes and inactivation of tumor suppressor genes and are considered one of the key hallmarks of cancer.⁶⁸ Some genomic signatures seem to persist after tumor development and throughout their progression and their histologic differentiation. The fact that smoking history leads to specific genomic alterations across different tumors also suggests a specific pathogenesis with genomic alteration resulting from a series of dysregulations in DNA repair mechanisms and chromosomal segregation.

The two theories are not necessarily mutually exclusive, and both random and nonrandom changes may be important. The progressive accumulation of mutations, loss of apoptotic control and regulation of cell proliferation, and the appearance of an abnormal number of chromosomes (aneuploidy) are associated with worsening dysplasia phenotypes and may reflect underlying dysregulation of mechanisms controlling genomic fidelity. In some lung tumors, mismatch repair deficiency leads to microsatellite instability at the nucleotide sequence level, whereas in other tumors, aneuploidy is the dominant feature.⁶⁹ Specific defects in DNA repair may also be present. Polymorphisms in DNA repair genes *XPB* (codon 312 Asp/Asp vs. Asp/Asn) are associated with impaired efficiency of DNA repair and apoptotic function in lung cancer.⁷⁰ Measures of genomic instability parallel rates of loss of heterozygosity⁷¹ and accumulation of other genomic abnormalities.⁶⁹ In the airways, progressively more severe and more frequent abnormalities are seen in preinvasive lesions. The progressive accumulation of genomic abnormalities associated with clonal growth among populations of tumor cells is well described. Recent reports use *array comparative genomic hybridization* (aCGH) to assess genomic instability; in these reports, in addition to numerical chromosome changes, smaller aberrations are found at specific chromosome loci.⁷² Clearly, genomic instability itself drives malignant progres-

sion, and this instability may itself be a target for prevention or therapy of lung cancer.

MUCOSAL RESPONSE TO INJURY, THE EMERGENCE OF CRITICAL MUTATIONS

Since the late 1970s, somatic mutations have been identified and associated with the development of cancer. These mutations, involving those of tumor suppressor genes or oncogenes, may or may not be critical events in the formation of the cancer. Epidemiologic data support the hypothesis that clones of cells accumulate several key mutations during oncogenesis. Proposed by Loeb,⁵⁵ the model of the mutator phenotype, a phenotype in which mutations develop faster than in normal cells, suggests that this propensity for rapid mutation may be required for multistage carcinogenesis and may be acquired by cells early on. This phenotype may also be hereditary.

DNA mutations may arise from a failure to repair DNA damage. In addition to damage and mutations due to environmental carcinogens, spontaneous errors of replication attributed to DNA polymerase take place at a rate of 1/10,000 to 1/100,000 base pairs. These intrinsic mutations may also be an important component underlying genomic instability and eventually tumor development. A recent analysis of 623 genes in 188 lung adenocarcinomas revealed more than 1000 somatic mutations, and those in 26 different genes were found to be mutated at significant frequencies.⁷³ Many of these mutated genes fall into a handful of common signaling pathways. We briefly comment on a few examples of these commonly acquired mutations in *KRAS*, *TP53*, *p16*, *BRAF*, *PIK3CA*, *epidermal growth factor receptor* (*EGFR*), and *anaplastic lymphoma kinase* (*ALK*).

KRAS mutations are among the most common mutations found in lung cancer. The mutations are found in 30% of adenocarcinomas of the lung,⁷⁴ but much less frequently in other subtypes. Mutations in *KRAS* lead to activation of several pathways. Ras proteins activate the RAF/MEK/ERK pathway, which mediates cell growth and cell cycle entry by phosphorylation of transcription factors (e.g., such as c-FOS, ELK1, and MYC); phosphorylation of the RSK (*ribosomal protein S6 kinase*) and MNK (*mitogen-activated protein kinase* [MAPK]-interacting serine/threonine kinase) family of kinases; and the *phosphatidylinositol-3-kinase* (PI3K)/protein kinase B (AKT) pathway, which controls cell survival, cell growth, and metabolism.⁷⁵ Mutant *KRAS* (most frequently, codon 12 G-T transversions) can transform airway epithelial cells⁷⁶ by activating the *extracellular signal-regulated kinase* (ERK)-MAPK and PI3K/AKT pathways. Because the *KRAS* mutation is found early in alveolar atypical hyperplasia, a presumed precursor lesion to adenocarcinomas, *KRAS* mutation may be an important step in the genesis of this subtype of lung cancer. The fact that mutant ras transgenic mice develop adenocarcinomas of the lung supports this hypothesis.⁷⁷

TP53 is a prototype tumor suppressor gene that is the most common genetic lesion in human cancers⁷⁸ and is thus well suited for analysis of the mutational spectrum in human cancers. The gene product p53 is a potent regulator of cell growth and DNA damage responses, and directly regulates the cell cycle via induction of p21. Mutations of

TP53 are most commonly seen in squamous carcinoma and small cell carcinoma of the lung. Mutations predominantly representing G to T transversions consistent with causation by bulky DNA adducts such as the polycyclic hydrocarbons are frequently found in the lungs of smokers.¹³ When the gene is mutated, the p53 protein can function as an oncogene. Mutated p53 exhibits a prolonged half-life, and the protein can be found to be overexpressed in about 50% of lung cancers by immunohistochemistry.⁷⁹ Although not consistently associated with prognostic significance, there is little doubt that *TP53* mutations play a key role in tumor development by dysregulation of cell cycle control and apoptosis.

p16, a cyclin-dependent kinase inhibitor, functions as a tumor suppressor and critical member of the *retinoblastoma* (Rb) cell cycle control pathway. The gene is inactivated in more than 40% of NSCLCs. Previous studies have demonstrated that point mutations, deletion or loss of heterozygosity (when one parental copy of a region is lost) on 9p21, or hypermethylation of the gene provides alternate mechanisms of inactivation in 30% to 50% of NSCLCs. In smokers, the loss of *P16* appears to be from different mechanisms than in nonsmokers. In tumors arising in smokers, *P16* was found to be lost due to point mutations or homozygous deletions, whereas in tumors from nonsmokers, *P16* was lost via promoter hypermethylation.⁸⁰ The relationship between the loss of *P16* and tobacco points to *P16* as another genetic target of cigarette smoke in the pathogenesis of lung cancer.

BRAF is a serine/threonine kinase that belongs to the RAS/RAF/MEK/ERK/MAPK pathway, and is important for transducing mitogenic signals from the cell surface. *BRAF* mutations were found in thyroid, colorectal, and lung cancer as well as in a majority of malignant melanomas.⁸¹ The percentage of *BRAF*-mutant lung cancers appears to be less than 5% and to be limited to lung adenocarcinomas.⁸² This observation has led to drug discovery programs dedicated to specific targeting of BRAF-dependent tumors. Trials investigating the efficacy of these agents are ongoing in several tumor types.⁸³ Whether *BRAF*-mutant lung cancer can be successfully treated with inhibitors targeting downstream pathway members of BRAF remains to be established.

PIK3CA, the gene encoding the catalytic subunit of the class-1a phosphoinositide-(3,4,5)-kinase, is an important component of the AKT antiapoptotic pathway. Mutations in this gene have been found in a large fraction of epithelial cancers.⁸⁴ Although the most frequently mutated oncogene in breast cancer, *PIK3CA* was found to be mutated in less than 5% of lung cancers. In several functional analyses, these mutations were found to be oncogenic by their ability to activate the AKT survival pathway.⁸⁵ Most recently, pre-clinical studies involving new generation PI3K-kinase inhibitors suggest that tumors carrying these mutations might be exquisitely sensitive to pathway inhibition.⁸⁶

The gene for the receptor tyrosine kinase EGFR is mutated in approximately 10% of white and 40% of East Asian patients with NSCLC,⁸⁷⁻⁸⁹ leading to constitutive activation of this growth factor receptor. These mutations are more common in patients who have never smoked, whose tumors are of adenocarcinoma histology, and who are of East Asian ethnicity. Exon resequencing in responders to the tyrosine

kinase inhibitors, gefitinib or erlotinib, revealed that most of them had deletion mutations in exon 19 or point mutations in exon 21 of the *EGFR* kinase domain, but patients not responding to these drugs only rarely had these mutations.⁹⁰ Inhibition of mutant EGFR is an example of successful therapeutic targeting of oncogenically activated tyrosine kinases in cancer. The presence and type of *EGFR* mutations indicate which patients will respond to therapy with EGFR inhibitors. Trials selecting patients on the basis of *EGFR* mutations have yielded response rates to EGFR inhibition therapy exceeding 70% and led to median overall survival exceeding 20 months.⁹¹⁻⁹³

Even though dramatic responses are frequently seen in patients with the common *EGFR* mutations, most patients initially responding to EGFR inhibitors eventually relapse. These relapses may be explained by additional mutations in *EGFR* or activation of other growth pathways. In certain cases, resistance has been found to be due to an activating mutation of *EGFR* at a second site. This mutation, T790M, is analogous to the T315I mutation of the murine leukemia viral oncogene homolog (ABL) that causes acquired resistance in chronic myelogenous leukemia patients who had initially responded to imatinib.^{94,95} An additional mechanism of acquired resistance is the *de novo* amplification of the MET receptor tyrosine kinase gene.^{96,97} Understanding the sources of acquired resistance may reveal strategies for prevention of resistance.

The ALK is a receptor tyrosine kinase that is aberrant in a variety of malignancies. ALK was originally discovered in anaplastic large cell lymphoma as part of a chromosomal translocation t(2,5), which fuses the C-terminal kinase domain of *ALK* encoded on chromosome 2p23 to the N-terminus of nucleophosmin on chromosome 5q35.⁹⁸ Subsequently, a variety of ALK fusion proteins have been found in multiple malignancies, including inflammatory myofibroblastic tumor and NSCLC.^{99,100} ALK fusion proteins are transforming and are highly susceptible to ALK inhibitors.¹⁰⁰ Indeed, the ALK tyrosine kinase inhibitor (TKI) crizotinib was recently approved for the treatment of ALK fusion-positive lung cancer.¹⁰¹ Because crizotinib has “off-target” activity against the ROS1 kinase, somatic activating ROS1 fusions may also be susceptible to crizotinib.¹⁰² Rearrangements involving another kinase, RET, may be targetable with RET TKIs.¹⁰³ Because of their ability to guide therapeutic decision making, *EGFR*, *KRAS*, *ALK*, *ROS1*, *RET*, *BRAF*, and *PIK3CA* mutation testing have become part of standard pathologic analysis of lung adenocarcinomas in many centers.

The efforts to characterize the genomes of major human cancer types¹⁰⁴ have revealed that, beyond known cancer-related genes, many additional genes are mutated in individual cancers. However, most of these mutations are found in only a single tumor, suggesting that each tumor contains an individual set of mutations contributing to tumorigenesis. Ding and coworkers⁷³ found between zero and 40 mutations in individual lung adenocarcinomas, with an average of 24.3 for those with a mutant *PRKDC* gene (involved in DNA repair) and 4.7 for those without this mutation. The average number of mutations for different tumors range significantly from 0.39 mutations per one million bases (mut/MB) to the highest in small cell lung cancer (7.34 mut/MB) followed closely by melanoma.¹⁰⁵⁻¹⁰⁸

Mutagens

Cigarette smoking may account for 85% of lung cancers. Approximately 1 in 10 life-smokers will develop lung cancer, suggesting individual differences in susceptibility.^{109,110} Environmental carcinogenesis resulting from tobacco smoke exposure is a complex process that can involve activation of procarcinogens that lead to DNA adduct formation and subsequent failure of DNA repair, which should normally remove these adducts. Studies comparing DNA repair capacity among newly diagnosed lung cancer patients and age-matched controls indicate significant differences between the two groups.¹¹¹

The majority of lung cancers are now diagnosed among ex-smokers.¹¹² This suggests that the accumulation of molecular damage during cigarette exposure initiates a cascade of events that lead to cancer even decades after smoking cessation. Risk factors for lung cancer include smoking, including total consumption, age of initiation, and years of smoking; occupational and environmental exposure (asbestos, uranium, radiation), diet (vitamin A, vitamin E, cholesterol), and host (familial aggregation) and genetic factors (see Chapter 52). Cigarette smoke is a complex mixture and includes substances that are responsible for DNA adduct formation such as polycyclic aromatic hydrocarbons, aromatic amines, and tobacco-specific nitrosamines. These form DNA adducts that may escape normal adduct repair mechanisms and result in heritable alterations in DNA sequence. For example, the conversion of G-C base pairs to T-A is involved in the activation of the *KRAS* oncogene and inactivation of the *TP53* tumor suppressor gene.¹⁷ The activated form of benzopyrene is the diol epoxide benzo(α)pyrene that can cause DNA adducts, leading to point mutations and single-strand chromatid breaks.¹¹³ A major concern is that people who start smoking at young ages seem to have greater amounts of permanent DNA alterations than smokers who start smoking later.¹⁴

ROLE OF INFLAMMATION IN LUNG TUMORIGENESIS

The tumor cell signaling pathways that trigger the uncontrolled proliferation, resistance to apoptosis, metastasis, and escape from immune surveillance are partially understood. In contrast, how inflammation and its control may participate in lung tumorigenesis remains more poorly understood.

The reason why some smokers develop *chronic obstructive pulmonary disease* (COPD), some develop lung cancer, and some develop both diseases remains unclear.¹¹⁴ Cigarette smoke contains high concentrations of oxidants and free radicals, together with thousands of particles. Local antioxidant and metabolizing enzymes inactivate many toxic species. Nuclear factor-κB activation and subsequent transactivation of inflammation-related genes appear to play a central role in both COPD and cancer.¹¹⁵ How some smokers remain free of disease while others develop COPD or cancer may be determined by the activation of genes in response to cigarette smoke.¹¹⁶ Following exposure to the same toxic smoke, individuals appear to progress toward disease along different paths. In those who develop lung cancer, genomic instability develops that causes further

chromosomal abnormalities resulting in clonal expansion of cells that have a growth advantage, whereas in those who develop COPD, an intense immune response and further inflammation predominate. The process by which these events diverge is unclear. More likely, heritable genetic polymorphisms that influence susceptibility to DNA or connective tissue damage, efficiency of DNA or connective tissue repair, the intensity of immune responses to constituents of tobacco smoke, intrinsic or acquired genomic instability, or the induction of factors that suppress immune surveillance likely determine the disease pathway taken.

Toll-like receptors (TLRs), which recognize a variety of pathogen-associated molecular patterns, are centrally involved in the initiation of the innate and adaptive immune responses. Recent evidence shows that functional TLRs are also expressed on a wide variety of tumors, suggesting that TLRs may play important roles in tumor biology, and are being evaluated as therapeutic targets.^{117,118} Activation of tumor cell TLRs not only promotes tumor cell proliferation and resistance to apoptosis but also enhances tumor cell invasion and metastasis by regulating metalloproteinases and integrins. Moreover, the activation of TLR signaling in tumor cells induces the synthesis of proinflammatory factors and immunosuppressive molecules, which enhances the resistance of tumor cells to attack by cytotoxic lymphocytes and leads to immune evasion. Thus, the TLR signaling pathways may be usurped by the neoplastic process to advance cancer progression, which suggests that targeting tumor TLR signaling pathways may open novel therapeutic avenues.

Inflammation and tumor-infiltrating inflammatory cells have been shown to induce and help sustain tumor angiogenesis and sustain cellular proliferation.¹¹⁹ COPD and its underlying chronic airway inflammation provide support of lung cancer growth.¹²⁰ Chemokines, a component of cancer-related inflammation, predispose to cancer by affecting multiple pathways of tumor progression, including leukocyte recruitment and function; cellular senescence; tumor cell proliferation and survival; invasion and metastasis.¹²¹ The inflammatory system is expected to provide valuable targets for the development of innovative therapeutic strategies.

ROLE OF VIRUSES IN LUNG TUMORIGENESIS

Viruses can cause lung cancer in animal models; such viruses, including SV40 large T antigen and polyomavirus large and middle T antigens, cause lung cancer in transgenic models. No common respiratory viruses have been conclusively incriminated in the development of human lung cancer, but several have been implicated. Human papillomavirus, for example, has been associated with lung cancer and, in particular, lung cancer arising in women.¹²² These results remain controversial because *The Cancer Genome Atlas*, a coordinated effort supervised by the National Cancer Institute to apply high-throughput genome analysis to the study of cancers, has not reported viral sequences in tumors. Similarly, controversy persists on the role of other viruses. Simian virus 40 has been suspected in the development of mesothelioma¹²³; Epstein-Barr virus has been suspected to be involved in the development of papillomas, mesotheliomas, and lymphomas of the lung;

the Jaagsiekte sheep retrovirus or a variant has been thought to cause adenocarcinoma in situ in humans as it does in sheep.¹²⁴ However, many polymerase chain reaction–based assays have attempted to correlate bronchogenic carcinomas with respiratory viruses without success. Recent advances in proteomics may be useful in studying the role of viral infection in airway epithelial cell transformation. The proteomic analysis of tumors may allow the identification of peptide sequences specific to pathogens otherwise unknown in tumorigenesis.

In recent reports, infectious agents associated with diseased human tissues have been discovered by high-throughput sequencing technologies.¹²⁵ However, identification of a nucleic acid sequence in a sample does not necessarily implicate an organism as causal in a disease. Viral nucleic acid may be found because of contamination of tissues, because of a subclinical infection unrelated to the disease, or because it is latent in human tissue but not actively causing illness (e.g., human herpesvirus and human papillomavirus).

NEUROENDOCRINE TUMOR DEVELOPMENT, GENOMICS OF SCLC

SCLC develops from neuroendocrine cells in the lung. The evidence for this is best established from mouse studies with deletion of *Rb* and *TP53*.^{126,127} In these studies, mouse SCLCs often arise in the lung epithelium, where neuroendocrine cells are located, and the majority of early lesions were composed of proliferating neuroendocrine cells. When *Rb* and *TP53* were deleted in nonneuroendocrine lung epithelial cells, mice did not develop SCLC.^{128,129}

Recent publications offer new molecular characterization of SCLC. Using comprehensive genomic analysis of SCLCs^{130,130a} with high-throughput sequencing techniques, Rudin and colleagues have demonstrated that SCLCs are composed of multiple known and new molecular abnormalities. They confirmed known SCLC molecular alterations to genes such as *TP53*, *RB1*, *PIK3CA*, *CDKN2A*, and *PTEN*. In addition, they identified other genes coding for proteins with a wide array of cellular functions such as the RAS family regulator, chromatin-modifying enzymes, transcription regulators, kinases, protein phosphatases of G-protein coupled receptors. Further genetic mutational clustering identified specific pathways at the epicenter of SCLC pathogenesis, which included PI3K, Hedgehog, NOTCH, mediator complex, glutamate receptor, DNA repair, and the SOX family. This study showed a high mutational frequency of several SOX genes and overexpression of SOX2 in close to 25% of the SCLCs analyzed. Lastly, they identified new mutations to genes coding for tyrosine kinases such as *FLT1*, *FLT4*, *KDR*, and *KIT* as well as several fusion proteins such as *RLF-MYCL1* which could be potentially targeted therapeutically.

In another integrative genomic analysis of 99 SCLC tumors and lines, Peifer and coworkers confirmed recurrent losses of the tumor suppressor genes *TP53* and *RB1* and novel amplifications of *FGFR1*, *MYCL1*, and *MYCN* in SCLC.¹⁰⁵ These findings were found to be similar to findings in *TP53/Rb1* conditional knockout mice that, in the absence of p53 and RB1 protein expression, developed several SCLCs expressing amplifications of *MYCL1*, *MYCN*, and *NFIB*. Exome sequencing, transcriptome sequencing, and genome sequencing confirmed that SCLCs have a high mutation rate (7.4 protein-altering mutations per MB) that

corresponds with tobacco-associated carcinogen exposure. From these studies, they identified *TP53*, *RB1*, *CREBBP*, *EP300*, *SLIT2*, *MLL*, *COBL*, and *EPHA7* as potential oncogenic drivers, which were classified into five major groups: (1) *receptor tyrosine kinases* (RTK), (2) PI3-kinase and p53 pathways, (3) cell cycle control, (4) histone modifiers, and (5) SLIT-ROBO signaling. Using reverse phase protein arrays, Byers and associates identified PARP1, a DNA repair protein and E2F1 coactivator, to be highly expressed at the mRNA and protein levels in SCLCs. PARP inhibition down-regulated key components of the DNA repair machinery and enhanced the efficacy of chemotherapy,¹³¹ justifying future clinical studies evaluating PARP and EZH2 inhibition, together with chemotherapy or other agents. These gene-centric approaches will have to be complemented by genome control studies, studies aimed at understanding gene regulatory mechanisms by investigating the whole genome structure, including chromatin structure and epigenetic alterations, and function. Understanding both the genes and their control will be necessary to resolve the molecular networks explaining the heterogeneity found in tumors and their functional implications.

Small cell lung cancer has worse clinical outcomes and no currently proven personalized therapy. SCLC and NSCLC account for 15% to 20% and 80% to 85% of annual lung cancer cases, respectively. SCLC is clinically more aggressive with an untreated median survival of 2 to 4 months.¹³² Despite initial complete responses exceeding 50%, the best combinations of chemotherapy and radiation result in less than 5% of patients surviving 5 years from initial diagnosis.¹³² Efforts to identify driver mutations, gene amplifications, or signatures with clinical utility in SCLC have thus far not translated to new therapies. In addition, prognostic or diagnostic markers for SCLC are scarce.¹³³⁻¹³⁵ Over the past decade, several molecular abnormalities have been described as indicators of chemotherapy resistance and poor prognosis in NSCLCs.¹³⁶ As described earlier, recent seminal studies have identified genomic aberrations in SCLC that will hopefully lead to successful therapeutic strategies.

Why is no targeted therapy available in SCLC? The discovery of new targets for early detection and for therapeutics has been hindered by the fact that SCLC is often detected late and tissue is rarely obtained for study because surgical resection is not standard therapy. Another major shortcoming associated with the slow progress has been the lack of sensitive and robust technology to detect the signatures of cancer cells from minute quantities of available tissues or serum. Recently, advances in genomic technology provide high-resolution, high-throughput tools to measure copy number, gene expression, DNA methylation, and nucleotide sequence in cancer have started to move the field forward.^{105,130,137} These reports predict rapid evolution in the understanding and management of SCLC.

OTHER MOLECULAR ALTERATIONS DRIVING THE TUMOR PHENOTYPE

CHROMOSOMAL CHANGES

Cancer cells are characterized not only by mutations but also by a series of other chromosomal aberrations including

deletions and amplifications.¹³⁸⁻¹⁴⁰ Although chromosomal aberrations have been linked to most tumors and are a characteristic of cancer,⁶⁸ chromosomal aberrations are recognized as increasingly complicated.^{11,141} Many of the observed alterations have been considered consequences instead of causes of lung cancer development. However, there are chromosomal regions with frequent losses found in regions coding for essential tumor suppressor genes and DNA repair genes that may be involved in the pathogenesis of several tumor types.¹⁴²

Chromosomal alterations in NSCLC have been measured by aCGH.^{66,67,143} Specific areas of amplification and deletion can distinguish squamous from adenocarcinoma of the lung and other subtypes. Among many areas of genomic abnormality, amplification of chromosomal region 3q26-3q29 was the most prevalent abnormality in squamous carcinoma of the lung. These studies confirm and refine previously documented copy number alterations in lung cancer using CGH analysis^{64,144} and show particularly common amplified regions on chromosomal arms 1q, 3q, 5p, 8q, 11q, 12p, 17q, and 20q.

Chromosomal abnormalities may have a role in classifying tumors. Attempts have been made to look comprehensively at the genome to identify tumors with common groups of genetic features that might provide biologic or clinical guidance beyond traditional classification by light microscopy. Single nucleotide polymorphism arrays have been developed that are able to analyze loss or gain of genetic material at very high resolution⁶⁷ and cancer genome sequencing efforts have uncovered common mutations.^{106,107,145,146} From genomic analyses, relatively small differences have been observed between squamous and adenocarcinoma of the lung. The most prevalent differences were found on chromosome 3q and include the p63 gene.^{143,147,148} Accumulation of specific chromosomal abnormalities has been correlated with clinical and pathologic data in NSCLC. Chromosomal abnormalities have been correlated with clinical outcome for a variety of cancers,¹⁴⁰ but often, the genes or networks responsible for the observed biology are very difficult to define and are only partly understood.^{146,149-151}

Chromosomal abnormalities may underlie the progression of cancer. Loss of chromosomal regions on chromosomes 3p and 9p have been recognized as early events and identified in preinvasive lesions and in the normal-appearing epithelium of smokers.^{152,153} In contrast, *TP53* and *KRAS* mutations have been seen primarily in later stages of preneoplasia or frank invasive lesions.¹⁵⁴ Amplification of large regions on the q arm of chromosome 3 has been characterized in invasive carcinomas^{64,66,144,155} and only recently in preinvasive lesions.¹⁴⁷ Patterns of chromosomal change may be specific to cigarette smoke. In fact, lessons have been learned from the molecular analysis of lung cancers from patients with and without a history of smoking. For example, *loss of heterozygosity* (LOH), the loss of a chromosome containing a wild-type gene when the gene on the other allele was previously mutated, at chromosome 3p14 was evaluated in smokers and ex-smokers. LOH at this site was found to be more frequent in current smokers (22/25 cases) than in former smokers (5/11 cases), and the high frequency in smokers correlated with a high metaplasia index.^{152,153} This implies that not only are these chromosomal changes frequent in normal-appearing bronchial

epithelia but also that cells with these changes may regress after smoking cessation and be replaced by cells without this damage. Patterns of lung cancer allelic loss have been investigated in detail and new regions of allelic loss have been identified using high-throughput technologies.⁷¹ Interestingly, chromosome losses such as LOH and chromosomal gains are more prevalent at all sites in cancers from smokers than from nonsmokers, indicating a greater chromosomal instability in the cancers from smokers.¹⁵ aCGH has been used to discover specific patterns of genomic alterations found in NSCLC that might be related to smoking history. Smoking-related genomic signatures were identified in NSCLCs and could be predicted with an overall 88% accuracy.²³ Lung tumors arising from current smokers had the greatest number of copy number alterations. The genomic regions most significantly associated with smoking were located within 32 regions and functionally associated with genes controlling the M phase of the cell cycle, the segregation of chromosomes, and the methylation of DNA. Understanding chromosomal abnormalities specific to cigarette smoke exposure may point to the etiology of smoking-induced lung cancer.

Specific translocation is another chromosomal abnormality found in lung cancer, but much less commonly than in hematologic or mesodermal tumors.^{156,157} Chromosomal translocations modify gene function through the deregulated expression of cellular proto-oncogenes without altering the structure of the protein product or by generating and expressing a chimeric protein with growth-promoting activities. Unbalanced translocations are also responsible for a large number of LOHs, which is a genetic event known to cause inactivation of tumor suppressor genes.¹⁵⁸ Dang and colleagues¹⁵⁹ identified a chromosome 19-15 balanced translocation associated with overexpression of *NOTCH3*, a protein that establishes an intercellular signaling pathway that plays a key role in development. The authors developed a transgenic mouse model overexpressing *NOTCH3* causing neonatal mortality with a phenotype suggestive of alveolar cell hyperplasia. These data suggest that *NOTCH3* overexpression prevents epithelial differentiation and this may play a significant role in promoting oncogenesis in a subset of lung cancers.¹⁶⁰

Similarly, recent findings are pointing towards new fusion genes such as *ALK*, *ROS1*, and *RET* (discussed earlier) with rapid translation toward novel therapeutics in lung cancer.^{100,102,161-163}

EPIGENETIC ALTERATIONS OF GENE EXPRESSION IN LUNG CANCER

DNA Adducts

DNA adducts are covalent modifications of the DNA that result from exposure to specific carcinogens and thus, the level of DNA adducts in normal cells can serve as a biomarker for a significant exposure to carcinogens. In addition to being markers of carcinogen exposure, DNA adducts may directly alter regulation of transcription of tumor suppressors or oncogenes.¹⁶⁴ Because DNA adduct levels in tumor tissue and in blood lymphocytes have been associated with lung cancer¹⁶⁵ and because these levels correlate with daily or lifetime cigarette consumption and do not

reverse after smoking cessation,¹⁶⁶ DNA adducts have been proposed as potential biomarkers of risk for lung cancer.

In an attempt to identify risk factors associated with the level of DNA adduct accumulation, Wiencke and associates studied DNA adducts in current and former smokers and found that, for current smokers, the most important variable in determining the level of DNA adducts was the number of cigarettes smoked per day.¹⁶⁴ In contrast, they found that for ex-smokers, the most important variable was age at initiation. Mechanisms responsible for the relationship between DNA adduct levels and age of initiation are unknown; the relative contribution of increased adduct formation at younger ages or perhaps decreased adduct removal by impaired DNA repair is yet to be determined. Prospective studies are needed to follow current and ex-smokers over time to determine the value of adduct levels in risk assessment.

DNA adducts have also been associated with risk of lung cancer. In a matched case-control study nested within the prospective Physicians' Health Study, there was an increased level of DNA adducts in active smokers who later developed lung cancer than in smokers who did not develop lung cancer.¹⁶⁷ The level of adducts has also been found to be more prevalent among female than male smokers. Women smokers may be at higher risk of developing lung cancer for a given tobacco exposure and women also seem to accumulate aromatic/hydrophobic DNA adducts at a faster rate than men.¹⁶⁸ (See Chapter 52.)

DNA Methylation

DNA methylation alters gene expression by increasing the density of methylation at promoter regions. In contrast to genetic mutations that require two hits to inhibit both alleles, aberrant methylation is a dynamic process over multiple division cycles and may cause increasing degrees of gene function loss over time. "CpG islands," the major targets of DNA methyltransferase, are associated with the transcription start sites in almost half of human genes.¹⁶⁹ Dense methylation of cytosines within CpG islands can cause heritable gene silencing.¹⁷⁰ Genomic DNA hypomethylation, leading to genomic instability, as well as promoter hypermethylation, leading to inactivation of tumor suppressor genes, have been shown to be common events in human cancer.¹⁷¹ Gain of methylation in normally unmethylated CpG islands surrounding gene transcription start sites is an increasingly recognized and important means by which gene expression is altered in tumors.¹⁷² The genes affected include more than half of the tumor suppressor genes that are known to cause familial cancers. Aberrant methylation can begin early in tumor progression and cause loss of cell cycle control (e.g., p16),¹⁷³ loss of mismatch repair function (e.g., MLH1), and loss of cell-cell interaction (e.g., E-cadherin). The exact mechanism by which hypermethylation may cause tumor progression is still unknown. In fact, there is still debate about whether methylation is a result of or a cause of gene function loss.¹⁷⁴

Promoter region hypermethylation has also been proposed as an excellent tumor marker. In lung cancer, methylated loci were found in both tumor and sputum DNA and have been detected in the sputum for up to 3 years before the diagnosis of cancer.¹⁷⁵ Recently, methylation of the

promoter region of four genes (*TP16*, *CDH13*, *RASSF1A*, and *APC*) in patients with stage I NSCLC was shown to be associated with early recurrence.¹⁷⁶ The recent effort in *The Cancer Genome Atlas* also reported the landscape of alterations in methylation across a large number of lung cancers.¹⁷⁷

Histone Deacetylation

Histone deacetylation is another mechanism of epigenetic control. Histones are nuclear proteins that package DNA and allow ribosomal access to the DNA. Acetylation of histone tails on the nucleosome is associated with chromatin unfolding and increased regional transcriptional activity. Histone deacetylases modulate chromatin structure by regulating acetylation of core histone proteins. Deacetylation of histones is thus associated with compacting the DNA and repressing transcription. In lung cancer cell lines, for example, deacetylation of histone 3 correlated with refractoriness to retinoic acid, a phenomenon related to RARbeta promoter methylation in a subset of cell lines.¹⁷⁸ Inhibitors of histone deacetylases have already been shown to decrease the level of a series of oncoproteins,¹⁷⁹ suggesting a potential role as antitumor therapeutic agents.

Regulation by miRNAs

Micro-RNA (miRNA) are a large family of single-stranded noncoding RNAs that direct the posttranscriptional repression of protein-coding.^{180,181} In a study analyzing 104 pairs of NSCLC and corresponding normal lung tissues, an expression profile of 43 miRNAs discriminated lung cancers from noncancerous lung tissues.¹⁸² Six miRNAs (hsa-mir-205, hsa-mir-99b, hsa-mir-203, hsa-mir-202, hsa-mir-102, and hsa-mir-204-prec) were differentially expressed in adenocarcinomas when compared with squamous cell carcinomas. Furthermore, high hsa-mir-155 and low hsa-let-7a-2 expression correlated with poor survival in lung adenocarcinomas. In another study of 143 surgically resected NSCLCs, low let-7 expression was also significantly associated with shorter survival, whereas overexpression of let-7 in the A549 lung adenocarcinoma cell line inhibited lung cancer cell growth in vitro.¹⁸³

Differentially expressed miRNA genes in NSCLC are frequently located in fragile sites of chromosomes highly prone to mutation and/or chromosomal regions with frequent copy number alterations, suggesting that differences in miRNA expression may be induced by genomic alterations. Because greater than 50% of miRNAs are present at cancer-related chromosomal regions, miRNAs are also suspected to play a role as oncogenes or tumor suppressor genes. miRNA expression profiles represent potential markers for lung cancer diagnosis, classification, and prognosis. Methodologic issues related to the reproducibility of the analytic platforms should be resolved soon.

PROTEOMIC ALTERATIONS

Changes in DNA and in RNA may not be reflected in changes in protein expression. In fact, recent advances in protein profiling have suggested a poor correlation between gene expression and protein expression. It is now well established that protein activity is often highly regulated by

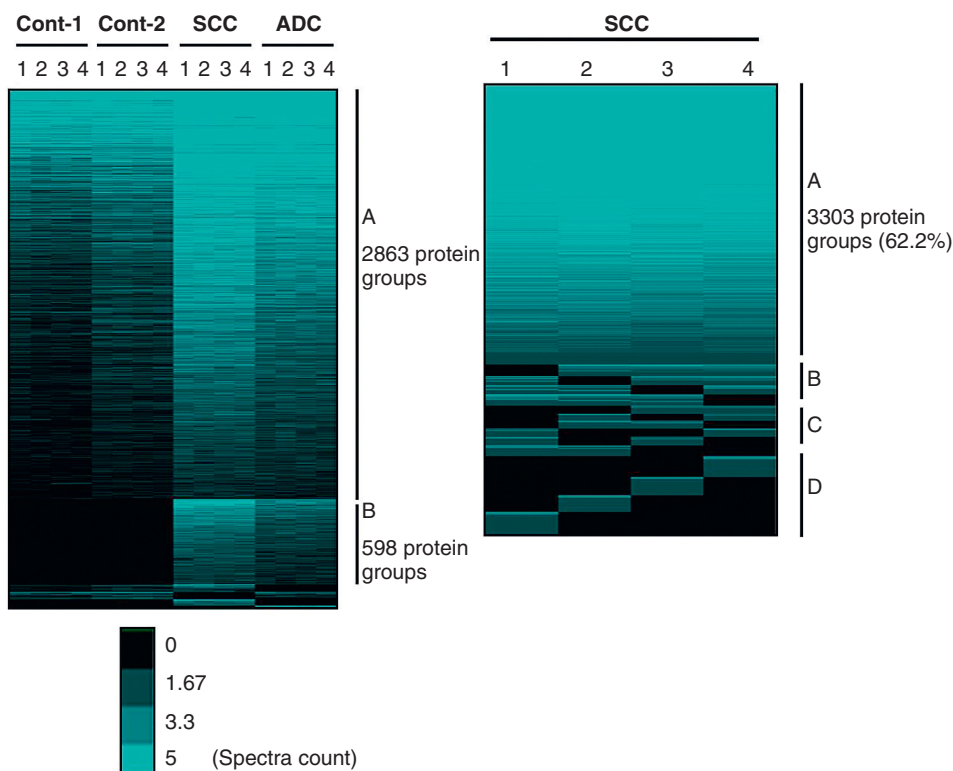

Figure 51-2 The shotgun proteomic method reproducibly identifies large numbers of proteins from clinical samples. *Left*, Heat map view of all identified proteins. Peptides were generated from three different histology pools including two control pools (Cont-1 and Cont-2), squamous cell carcinoma (SCC), and adenocarcinoma (ADC) pools. The number of protein groups (2863) found across all pools (top), are shown at the upper right side of the panel. Protein groups present only in the SCC and ADC tumor pools (598) (bottom), are shown at the lower right. Control: Noninvasive lung tissue. *Right*, We identified proteins in the SCC pool from four repeated experiments as indicated by the numbers 1 through 4 shown above each row. Out of the 5310 protein groups identified, 3303 (62.2%) protein groups were observed in every experiment (A), and 487 (9.2%) protein groups were observed in three experiments (B). The number of proteins observed in two experiments (C) and one experiment (D) was 597 (11.2%) and 923 (17.3%), respectively. The blue lines in each row represent identified protein groups. The intensity of each line is indicative of the spectra counts for each protein group with the scale shown at the bottom of the figure. (Adapted from Kikuchi T, Hassanein M, Amann JM, et al: In-depth proteomic analysis of nonsmall cell lung cancer to discover molecular targets and candidate biomarkers. *Mol Cell Proteomics* 11:916–932, 2012.)

posttranslational modifications such as proteolysis and phosphorylation. Neither protein expression levels nor posttranslational modification can be assessed by genomic or cDNA microarray technologies, prompting interest in evaluation of protein expression, commonly referred to as “proteomics.”

Lung cancer has been studied by several proteomic methods including two-dimensional gel electrophoresis, mass spectrometry, and immunohistochemistry to identify biomarkers in tumors.¹⁸⁴⁻¹⁸⁶ or in biologic fluids such as bronchoalveolar lavage¹⁸⁷ of patients with or without cancer. Matrix-assisted laser desorption ionization profiling is rapid, high throughput, but detects only the most abundant proteins of relatively low molecular weight and does not enable direct identification when applied to complex proteomes. Two-dimensional gel-based analysis suffers problems of interlaboratory reproducibility and throughput. Mass spectrometry has an even lower throughput, but yields confident identification of large numbers of proteins from every cellular compartment.

Advances in proteomic analysis of human samples are driving critical aspects of biomarker discovery and the identification of molecular pathways involved in disease etiology. Our group has used a standardized *shotgun pro-*

teomic analysis method, which consists of identifying proteins in complex mixtures using a combination of high performance liquid chromatography and mass spectrometry, for profiling the two major subtypes of NSCLC and normal lung tissues (Fig. 51-2). With this approach, 3621 proteins were identified from the analysis of pooled human samples of squamous cell carcinoma, adenocarcinoma, and control specimens. In addition to proteins previously shown to be implicated in lung cancer, multiple new proteins were found of potential interest as therapeutic targets or diagnostic biomarkers, including some that were not identified by transcriptome profiling.¹⁸⁸ Up-regulation of these proteins was confirmed by multiple reaction monitoring mass spectrometry. This proteomic technology platform allows deep mining of lung tumor proteomes, enabling the identification of novel, previously undetected biomarker candidates and potential targets for therapy, such as SLC1A5, a neutral amino acid transporter that is responsible for more than 50% of glutamine transport into lung cancer cells.¹⁸⁹ SLC1A5 is also located at the cytoplasmic membrane and its inhibition decreased cell growth and viability in lung cancer cells. Such approaches may uncover novel and hopefully useful biomarkers of lung cancer.

Reverse phase protein arrays¹⁹⁰ are a means to validate protein biomarkers in biologic specimens. The major advantage is that it allows rapid evaluation of known signaling pathways in lung cancer and it requires a minute amount of tissue.^{131,191} The limitation is that this method is a targeted one and dependent on the validation of specific antibodies.

STRATEGIES TO DEEPEN OUR UNDERSTANDING OF LUNG CANCER

HIGH-THROUGHPUT PROFILING TECHNIQUES

Expression Arrays to Next Generation Sequencing

Because DNA ultimately affects cellular behavior via proteins translated from the RNA, RNA expression patterns may be more relevant than either DNA copy number or epigenetic DNA changes. The microarray technology developed in the mid-1990s offers the hope that a fingerprint of the genetic expression of these tumors can be developed and then associated with clinical features. Beyond allowing for better classification of lung cancers, this technical advance in profiling gene expression opens a window into the world of tumor behavior (disease progression, recurrence, response to therapy) as well as to the mechanisms of tumor development. Tumor gene expression profiles are also influenced by the surrounding nonmalignant cells and so profiling both the tumor and nontumor will allow for the study of the regulatory role of both entities.¹⁹²

Expression array data have provided new ways to distinguish and classify tumors. Selected genes allow the discrimination between primary lung cancer and metastasis of extrapulmonary sites.¹⁹³ Studies of expression profiles of adenocarcinomas of the lung using commercially available gene chips¹⁹³ or custom arrays^{194,195} have identified different classes of tumors, albeit with some overlap. For example, four classes of adenocarcinomas were found to have specific prognoses and expression signatures. These were characterized respectively by their (1) expression of cell cycle or proliferation genes, (2) expression of neuroendocrine markers, (3) expression of markers of alveolar origin, and (4) expression of ornithine decarboxylase or glutathione S-transferase.¹⁹³ The neuroendocrine subclass was found to have a clinical outcome significantly worse than the others. These subclass differences may suggest possible new therapies targeted to these subsets and explain why tumors that superficially seem similar may respond quite differently to therapy. For example, when cDNA microarrays were used to study neuroendocrine tumors, a poor correlation was found between genes expressed in carcinoid and SCLC,¹⁹⁶ tumors that may be morphologically similar but that behave very different clinically.

In sum, since the late 1990s, we have learned that the somatic molecular alterations in cancers yield signatures that can be used for subclassification^{193,195} or for predicting patient survival,^{195,197} risk of recurrence,¹⁹⁸ and response to therapy.¹⁹³ However, these signatures have not always withstood independent validation.¹⁹⁹

Advanced Proteomic Strategies

Mass spectrometry-based technologies are capable of very high throughput, allowing a sample to be analyzed in seconds and with a higher tolerance for salts, buffers, and other biologic contaminants. Because of these attributes, matrix-assisted laser desorption ionization mass spectrometry has been used to study proteins/peptides in serum,²⁰⁰⁻²⁰³ urine,²⁰⁴ tissue extracts,^{205,206} whole cells,²⁰⁷ and laser-captured microdissected cells.²⁰⁸ These profiling experiments have been applied to a series of biologic specimens. In one matrix-assisted laser desorption ionization mass spectrometry study from our group,²⁰⁹ hierarchical clustering of data from lung cancers and normal tissues allowed the identification of patterns distinguishing between tumor and normal as well as between histologic subgroups. Shotgun proteomic approaches allow the survey of increasing numbers of proteins and uncovers new molecular characteristics of lung cancers, as recently demonstrated in NSCLC.¹⁸⁸ Using an integrative proteomic and transcriptomic analysis, molecular differences between SCLCs and NSCLCs have been identified, supporting the potential role for PARP1 and EZH2 in SCLC.¹³¹ In general, however, because of a lack of reproducibility between platforms and institutions, proteomic profiling, unlike genomic signature profiling, has not yet made a major impact in clinical practice.²¹⁰⁻²¹²

Proteomic profiling in biologic fluids or tissue samples has also been studied, but is not without challenges. The complexity of the sample composition and the predominance of few abundant proteins in the sample that can mask lower abundant proteins currently limit the utility of this approach. A newer serum proteomic platform has been tested in retrospective studies and shown to have the ability to predict whether or not NSCLC patients will benefit from the EGFR TKI erlotinib.²¹³⁻²¹⁵ Future efforts to analyze specific proteins or protein signatures in serum or other fluids has potential for diagnosis, prediction of therapeutic response and monitoring.

MOLECULAR NETWORKS—SYSTEM BIOLOGY

To determine the most informative molecular targets from high-throughput assays, increasingly sophisticated analytic tools are being developed. These analytic tools help define biologic processes, cellular components, or molecular pathways as well as provide gene ontology information about genes of interest; such analytic tools include WebGestalt,²¹⁶ Pathway Studio, and Ingenuity. The Kyoto Encyclopedia of Genes and Genomes is a knowledge base for systematic analysis of gene functions in terms of the networks of genes and molecules.²¹⁷ Although most pathway and network analysis tools are gene-centric, tools for combining and integrating multidimensional information at various levels are rapidly developing.²¹⁸ Network analysis helps identify central genes or proteins, called *hubs*, that link many others in the network. One can assume that mutations in regulatory (hub) genes or proteins, for example, are more likely to cause disease than mutations in those less connected and peripheral in the network.²¹⁹ These hubs may also be target sites for therapy. Therefore, quantitative systems biology applied to cancer offers a unique approach for defining the pathogenesis, and developing

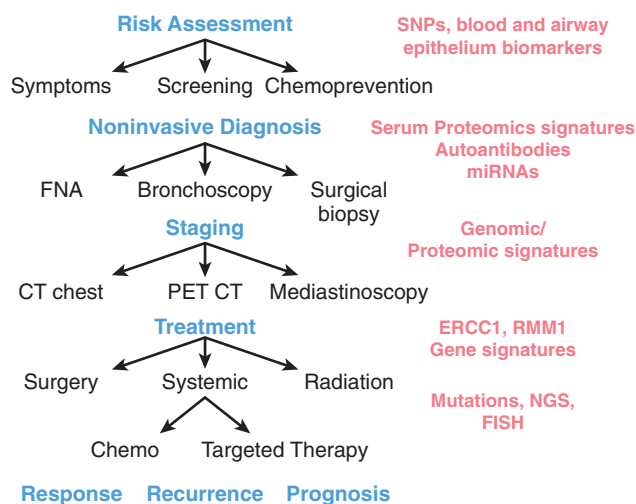

Figure 51-3 Future applications envisioned for biomarker-driven personalized management of lung cancer. At each step in the course of the management of lung cancer, important clinical decisions are made. Biomarkers of risk, diagnosis, prognosis, and response to therapy are becoming available and are already driving a personalized approach to lung cancer. Examples of such candidate biomarkers are provided in the figure at points in the decision tree where they may affect decision making in the near future. ERCC1, excision repair cross-complementation group 1; FISH, fluorescent in situ hybridization; FNA, fine needle aspiration; miRNAs, microRNAs; NGS, next generation sequencing; RMM1, ribonucleotide reductase; SNPs, single nucleotide polymorphisms.

individualized (personalized) treatment strategies that can take full advantage of modern molecular pathobiology and the comprehensive data sets that are rapidly becoming available for populations and individuals.

TRANSLATING LUNG CANCER BIOLOGY TO THE CLINIC

BIOMARKERS

Biomarkers are measurable products of tumors that can assist in the diagnosis (identification of cases), prognosis (correlation with outcome independent of interventions), or prediction (associated with outcome after a specific intervention). It is clear that lung cancer outcomes could be improved by high-quality biomarkers addressing each of these categories (Fig. 51-3). The biggest strides made to date have been in choosing treatments for patients with advanced lung cancer. However, to decrease lung cancer deaths, we need to devise biomarker-driven strategies for prevention, early detection, and treatment of early-stage lung cancers.

The discovery of biomarkers for early-stage lung cancer has been hampered by the slow onset of lung cancer and the lack of screening tests to identify early disease, although with the recent positive screening trial of low-dose *computed tomography* (CT) scans for heavy smokers, we are hopeful that the biologic samples collected from participants will be a useful resource for discovery for biomarkers.^{220,221} The assumption underlying the concept of biomarkers is that certain molecular characteristics of the lesions are highly correlated with specific, clinically-relevant biologic states.

Table 51-2 Characteristics of a Successful Diagnostic Biomarker

Measurable, noninvasive, with strong performance characteristics (with emphasis on positive and negative predictive values), robust, reproducible, and biologically relevant
Proven to add clinical value to current standards *and* to trigger a clinical decision
Adopted by the clinical community for the benefits it affords
Competitive in terms of cost and insurance reimbursement

These characteristics include changes in expression levels of genes and proteins and their posttranslational modifications. Detection of cancers at early stages maximizes survival, and identification of blood-borne markers would lead to minimally invasive tests. The best biomarkers are those that are reproducibly measured, that are related to the disease process, and that trigger a clinical decision resulting in improved clinical outcomes (Table 51-2). Despite an intense search for such biomarkers, there are none currently validated for the early diagnosis of lung cancer.²²²⁻²²⁴

Biomarkers based on the earliest known molecular abnormalities found in lung cancer could aid the early detection of lung cancer. Sputum sample analysis for DNA methylation, miRNAs, or chromosomal abnormalities by fluorescence in situ hybridization may represent approaches suitable for early detection. New detection methods such as exhaled breath condensate for tumor metabolites^{225,226} may be found to be efficient ways of assessing high-risk individuals. As alluded to earlier, early detection by low-dose CT scanning has been shown to be effective in lowering both overall and cancer-specific mortality in the National Lung Cancer Screening Trial.²²⁰ The addition of molecular studies may significantly increase the sensitivity and specificity of this new strategy for early detection.

Biomarkers may also provide prognostic and predictive information. Expression array signatures and serum proteomic assays have been discussed previously. Polymorphisms or expression of DNA repair genes (e.g., ERCC and RRM) have been associated with predicting response to chemotherapy,²²⁷ but also have been shown to have significant practical obstacles in terms of the performance reliability of antibody-based immunohistochemical tests,²²⁸ raising questions about their clinical utility.²²⁹ Cyclooxygenase-2 expression and urinary prostaglandins have been associated with benefit from COX inhibitors^{230,231} and are being further studied.

PERSONALIZED MEDICINE AND MOLECULAR THERAPEUTICS

The biggest impact of biomarkers in NSCLC clinical care has been in testing patients with advanced or metastatic disease for the presence of “driver” genotypes, which can then be matched to corresponding targeted therapies (Fig. 51-4). The term *driver* genotype refers to a crucial, necessary biologic change, usually a gain-of-function imparted by a gene mutation, amplification, or translocation. This driver is oncogenic and plays a critical role in the signaling that drives the malignant phenotype of the cancer. A wide range

of such driver genotypes have been found consistently in NSCLC, predominantly in adenocarcinoma tumors but to some extent in squamous cell cancers as well.^{232,233} Genotype screening of large patient populations has demonstrated that the driver genotypes tend to be mutually exclusive, suggesting that indeed these changes play a role in the early development of cancer and confirming the

notion that genotypic biomarkers can be used to distinguish one subtype of lung cancer from another. Clinical standards of diagnosis for NSCLC are evolving to take genotyping into account at the time of diagnosis; multiplexed platforms are being developed to accomplish testing in a time, money, and tissue-efficient manner.²³⁴ The genotype information is then used to match patients with targeted therapies, typically small molecular inhibitors that specifically block signaling of the driver pathway. A friendly tool available online at “www.mycancergenome.org” provides such support in an unprecedented way.²³⁵

There are several *EGFR* mutations (most commonly deletions in exon 19 and the L858R point mutation in exon 21) that have been found in adenocarcinomas among patients with a low smoking history.⁸⁷⁻⁸⁹ *EGFR* mutations are much more frequent in patients originally from East Asian nations, for reasons that are unknown; about 10% to 15% of North American and European lung cancer patients have *EGFR* mutations, whereas in Japan the proportion is 50% or greater.²³² These mutations lead to a constitutive activation of the EGF receptor and its downstream growth pathways and patients with *EGFR* mutations can respond in a dramatic way to the approved *EGFR* TKIs gefitinib, erlotinib, and afatinib (Fig. 51-5 and Table 51-3).^{92,211,236} For context,

Figure 51-4 Pie chart showing the percentage distribution of genetic abnormalities in lung adenocarcinoma. Treatment decisions about lung cancer have shifted from those based only on histology to those incorporating genetic alterations. As seen in this pie chart, the genome of lung cancer is being chipped away, with discovery of driver mutations that lead to constitutively active signaling proteins and provide a target for therapy. The most recently identified *KIF5B-RET* fusion subset, which accounts for approximately 1% of this distribution, is boxed. *NRAS*, neuroblastoma *RAS* viral (v-ras) oncogene homolog; *MAP2K1*, mitogen-activated protein kinase 1; *AKT1*, v-akt murine thymoma viral oncogene homolog 1; *PIK3CA*, phosphoinositide-3-kinase, catalytic, α polypeptide; *BRAF*, v-raf murine sarcoma viral oncogene homolog B1; *HER2*, human epidermal growth factor receptor 2; *EGFR*, epidermal growth factor receptor; *KRAS*, v-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog. (From Pao W, Hutchinson KE: Chipping away at the lung cancer genome. *Nature Med* 18:349–351, 2012.)

Table 51-3 Molecular Targets in Lung Cancer	
Characteristics of Cancer	Possible Molecular Targets
Self-sufficient cell growth	EGFR, PIK3CA, PDGFR, MAPK, EML4ALK, ROS1, ALK, RET, HER2, BRAF, MET
Insensitivity to anti-growth	SMADs, Rb, cyclin-dependent kinases, MYC
Limitless replicative potential	p53, Rb, hTERT, EML4-ALK
Evading apoptosis	KRAS, p53, BCL-2, caspases, FAS, TNFR, DR5, IGF/PI3K/AKT, mTOR, PTEN, MET
Sustained angiogenesis	NF- κ B, VEGF, TGF- β , α v β 3, thrombospondin-1, HIF1 α

AKT, protein kinase B; EGFR, epidermal growth factor receptor; EML4-ALK, echinoderm microtubule associated protein like 4-anaplastic lymphoma kinase; HIF1 α , hypoxia inducible factor 1 alpha; IGF, insulin-like growth factor; MAPK, mitogen-activated protein kinase; mTOR, mammalian target of rapamycin; NF- κ B, nuclear factor- κ B; PDGFR, platelet-derived growth factor receptor; PI3K, phosphatidylinositol-3-kinase; pRb, retinoblastoma protein; PTEN, phosphatase and tensin homologue gene; TGF- β , transforming growth factor- β ; VEGF, vascular endothelial growth factor.

Figure 51-5 A response to anti-epidermal growth factor receptor (EGFR)-targeted therapy. Axial chest CT scan of a woman with chemotherapy-refractory adenocarcinoma shows a dramatic response to gefitinib (*EGFR* tyrosine kinase inhibitor) after 2 months of treatment (A, before treatment; B, after treatment). This woman was a never-smoker of Asian ethnicity with an activating *EGFR* mutation.

Table 51-4 Targets Identified in Lung Cancer Along with Current or Potential Therapies

Driver Genotype	Targeted Therapies
<i>EGFR</i> mutations	Approved <i>EGFR</i> TKIs: gefitinib, erlotinib and afatinib Experimental <i>EGFR</i> TKIs: dacomitinib, CO-1686, AZD9291
<i>ALK</i> translocations	Approved <i>ALK</i> TKIs: crizotinib Experimental <i>ALK</i> TKIs: LDK378, AP26113, CH5424802, X-396
<i>ROS1</i> translocations	Experimental <i>ROS1</i> TKIs: crizotinib
<i>MET</i> amplification	Experimental <i>MET</i> TKIs: crizotinib
<i>BRAF</i> mutations	Experimental <i>BRAF</i> TKIs: dabrafenib, vemurafenib
<i>HER2</i> mutations or amplification	Experimental <i>HER2</i> monoclonal antibodies: trastuzumab Experimental <i>HER2</i> TKIs: afatinib
<i>KRAS</i>	Experimental <i>MEK</i> TKIs: selumetinib, trametinib

the response to first-line chemotherapy for lung cancer patients is approximately 20% to 35% and the median *progression-free survival* (PFS; how long patients remain on treatment without progressing) is about 5 to 6 months.^{237,238} An *EGFR* mutation-positive patient typically has a 75% response rate to an *EGFR* TKI with a corresponding PFS of 10 to 13 months. In a series of prospective randomized trials, it has been shown convincingly that initial treatment of advanced lung cancer in patients with *EGFR* mutations with an *EGFR* TKI instead of with standard chemotherapy significantly improves PFS and quality of life; this has now become the standard of care.^{212,239,240}

Translocations that result in the apposition of the *ALK* receptor tyrosine kinase gene near the *EML4* or other similar promoter regions have been identified in about 5% of NSCLC cases, again most commonly found in patients with a low smoking history.^{100,241} *ALK* rearrangements confer sensitivity to the *ALK* TKI crizotinib with an approximate 70% response rate and a PFS of 10 months (Table 51-4).^{101,242} Patients with *ALK* translocations previously treated with chemotherapy have been randomized to crizotinib versus standard second-line chemotherapy; crizotinib was found to be more effective in term of response and PFS.²⁴³ In addition, a retrospective analysis suggests that patients with *ALK* translocations treated with crizotinib have an improved overall survival compared to patients that were unable to receive crizotinib or were diagnosed and treated prior to the availability of crizotinib.²⁴⁴ This is an important issue because targeted therapies proven to yield dramatic responses in a genotype-defined population pose an ethical dilemma for future randomized trials, because it is no longer feasible to randomize patients away from the effective targeted therapy without allowing crossover at the time of progression. The *ROS1* receptor tyrosine kinase can undergo an activating translocation in 1% or less of NSCLC cases. Given the homology of *ROS1* to *ALK*, the TKI crizotinib also happens to be a specific and effective inhibitor for this subset of lung cancer patients.¹⁰² Interestingly, crizotinib also inhibits the *MET* tyrosine kinase, and about 1% or less of NSCLC patients have a driver genotype characterized by high-level amplification of *MET*. Case reports have

described patients with this genotype who respond to crizotinib therapy.²⁴⁵

Even though more common in melanoma, *BRAF* mutations are also found in about 1% of NSCLC patients.^{232,246} Both *HER2* mutations and *HER2* amplification are seen in a small percentage (1% to 2%) of lung cancer patients and are associated with response to the *HER2* monoclonal antibody trastuzumab and the TKI afatinib.^{247,248} Other rare driver genotypes are emerging in rapid succession.

KRAS mutations are the most common genotype but have so far been refractory to therapeutic targeting. In colon cancer, the presence of *KRAS* mutation has been a robust negative predictor for *EGFR*-targeted therapies (mainly monoclonal antibodies),²⁴⁹ but in NSCLC it has been less clear that *KRAS* mutations should disqualify patients for *EGFR* therapy.^{250,251} Development of downstream signaling inhibitors looks like a potential promising strategy for *KRAS* mutants and a randomized phase 2 study of docetaxel chemotherapy with or without the *MEK* inhibitor selumetinib showed an interesting increase in response rate and in PFS.²⁵²

Harnessing the immune system to attack cancer has long been a dream of physicians, but progress has historically been slow. However, recently, new treatment options in the form of “checkpoint” modulators have emerged as highly promising therapeutic options. *Programmed death 1* (PD-1) protein, a T-cell coinhibitory receptor, and one of its ligands, PD-L1, play a pivotal role in the ability of tumor cells to evade the host’s immune system. Blockade of interactions between PD-1 and PD-L1 enhances immune function in vitro and mediates antitumor activity in preclinical models. In two pivotal phase I trials, antibodies against PD-1²⁵³ and PD-L1²⁵⁴ have led to remarkably high response rates with durable clinical benefit. CTLA-4 is another protein receptor that down-regulates the immune system. The anti-CTLA-4 antibody, ipilimumab, was approved for use in melanoma²⁵⁵ and is being tested in lung cancer. Combinations of anti-PD-1 and anti-CTLA-4 antibodies may be even more active, as has been shown in melanoma.²⁵⁶ Anti-PD-1 and -PD-L1 antibodies may be most effective in tumors expressing the proteins,^{254,257} but the biomarkers have not yet been established as definitive predictors of response.

MECHANISMS OF RESISTANCE

One of the most active areas of research currently in the field of targeted therapy for lung cancer is how to overcome acquired resistance. The genotypes with the most proven success in treatment with targeted agents (*EGFR* mutations and rearrangements in *ALK* and *ROS1*) have also demonstrated that resistance is acquired after 1 to 2 years for most patients. Resistance is often in the form of a point mutation at the gatekeeper location within the RTK,^{94,95,210,258,259} but may also be in the form of a bypass track, or detour using another cancer signaling pathway.^{96,97,258,260} Evolution of the cancer histology from adenocarcinoma to small cell lung cancer has been noted in some patients with *EGFR* mutations with acquired resistance to *EGFR* TKIs but the mechanism is not well understood.^{260,261} Several therapies for acquired resistance to therapy are being studied, primarily in NSCLC with *EGFR* mutations and *ALK* rearrangements.

Key Points

- Lung cancer in smokers is preceded by an accumulation of genetic, epigenetic, and posttranslational abnormalities in the entire bronchial epithelium, showing the validity of the field cancerization concept.
- Lung cancer in never-smokers is less well understood. Nonetheless, the risk for either type of cancer (among smokers or nonsmokers) appears to have a hereditary predisposition, as seen, for example, with genetic alterations in the nicotinic acetylcholine receptors.
- Sequencing of hundreds of candidate genes in adenocarcinomas has shown that there are between zero and 40 lesions in individual lung tumors, which often fall into a handful of previously defined pathways.
- The most common genes altered in lung cancer are *TP53* and *KRAS*, for which effective targeted therapies do not yet exist.
- For some genetic lesions, particularly driver mutations or translocations in *EGFR*, *ALK* and *ROS1*, targeted therapies exist and striking clinical effectiveness has been observed.

INTRODUCTION

As the leading cause of cancer death in the world, lung cancer is currently a public health problem of enormous magnitude. In 2008 more than 1.6 million people were newly diagnosed with lung cancer, comprising 13% of all new cancer diagnoses; furthermore, 1.4 million, or 18% of all cancer deaths, were from lung cancer.¹ In contrast, at the start of the 20th century, lung cancer was considered a rare disease. However, its epidemic rise across the first decades of that century was soon identified as clinicians began to provide care for increasing numbers of patients with lung cancer and routine vital statistics documented rising mortality. Although tobacco had been widely used throughout the world for centuries, the pandemic of lung cancer followed the introduction of manufactured cigarettes with addictive properties, which resulted in a new pattern of sustained exposure of the lung to inhaled carcinogens.² Epidemiologic research linked smoking to lung cancer in investigations that began in the 1930s and provided convincing and consistent evidence from the 1950s forward.³ Whereas its predominant cause—tobacco smoking—is now well known, there are other causes of lung cancer as well, some acting in concert with smoking to increase risk synergistically.

This chapter provides a summary of the epidemiologic evidence on lung cancer. It is based primarily on summaries of the evidence prepared by expert committees, and it includes findings of representative and particularly informative studies. Syntheses have been periodically carried out by expert review groups, dating back to reports such as the 1962 report of the Royal College of Physicians⁴ and the landmark 1964 Report of the U.S. Surgeon General.⁵ More recent reports include those prepared by the International Agency for Research on Cancer in 2004,⁶ the 2004 and 2006 reports of the Surgeon General on active and passive smoking, respectively,^{7,8} and the 2010 report of the Surgeon General on the mechanistic basis of smoking-caused pathogenesis.⁹ The 2014 U.S. Surgeon General's Report commemorated the 50th anniversary of the landmark 1964 report and once again updated the evidence on the adverse health effects of cigarette smoking.^{9a} The U.S. Surgeon

General's Reports have provided evidence syntheses and inferences that have guided the conclusions that active and passive cigarette smoking are causally associated with the risk of lung cancer.^{9b} In turn, the evidence on these topics have been historically important in the development of epidemiology.^{9b}

PATTERNS

TEMPORAL TRENDS

Because of the high case-fatality rate of lung cancer, incidence and mortality rates are nearly equivalent; consequently, routinely collected vital statistics provide a long record of lung cancer. We are amidst an epidemic of lung cancer that dates to the mid-20th century (Fig. 52-1).^{10,11} The epidemic among women followed that among men, with a sharp rise in rates from the 1960s to the present, making lung cancer the most frequent cause of female cancer mortality in the United States.¹² The epidemic among women not only arose later but also will not peak as high as among men because smoking prevalence crested at substantially lower levels among women than among men.¹³⁻¹⁵

Trends of age-specific lung cancer mortality rates in the United States show differing epidemic patterns in men than in women (Fig. 52-2).^{14,16-19} In the older age groups, the rates continue to increase in both sexes, but the rates of increase are decelerating more in men than in women. The rates of lung cancer are now decreasing in the younger age groups, more for men but also becoming evident in women.¹⁴

Notable shifts have taken place in the incidence rates of lung cancer by histologic type.²⁰ After steadily increasing in incidence between 1973 and 1987, adenocarcinoma supplanted squamous cell carcinoma as the most frequent form of lung cancer (Table 52-1).^{20,21}

RACE AND ETHNICITY

In the United States, whereas lung cancer incidence rates and mortality rates are similar among African American women and white women, incidence rates are 26% higher

and mortality rates are 23% higher in African American men than in white men.²² A marked reduction in cigarette smoking among African American youths²³ forecasts a possible reversal of this trend. In addition, lung cancer mortality rates among African Americans and non-Hispanic whites are significantly higher than rates among Hispanics, Native Americans, and Asian/Pacific Islanders.^{24,25} However, racial differences in historical patterns of cigarette smoking do not fully account for the racial disparities in lung cancer incidence and mortality rates.²⁶ The high rates in African Americans may be partially due to greater

susceptibility of African American smokers to smoking-induced lung carcinogenesis.²⁷ The higher mortality rates of lung cancer in African Americans than in white Americans reflect not only their higher incidence rate but also poorer survival. In 2009, the 5-year relative survival rate was 19% lower in African Americans than in white Americans.

GEOGRAPHIC PATTERNS

Lung cancer is the most commonly diagnosed cancer worldwide,^{27,28} but its geographic distribution shows marked regional variation²⁹: age-standardized incidence rates vary over a wide range, more than fourfold among men and fivefold among women (Fig. 52-3).³⁰ This marked variation in rates cannot be explained on the basis of diagnostic practices and data quality alone. Lung cancer tends to be most common in developed countries, particularly in North America and Europe, and less common in developing countries, particularly in Africa and South America.³¹ However, the lung cancer epidemic is on the rise in the developing world.³²

The epidemic of tobacco addiction in China illustrates the ongoing trend of a shift in the global lung cancer burden from high-income Western countries to low- and middle-income countries, particularly in Asia. In 2008, newly diagnosed lung cancers in developing countries exceeded the number in developed countries by 22% (884,500 and 724,300, respectively).³³ The situation in China is particularly serious. Due to a striking increase in active smoking, Chinese males are a population of particular concern. Per capita cigarette consumption in Chinese men increased from one cigarette per day in 1952, to four in 1972, and

to 10 in 1992.³⁴ As a consequence, the lung cancer mortality rates have already increased 27% from 1990 to 2010³⁵ and will continue to rise substantially in the absence of aggressive tobacco control measures. The increase in lung cancer among Chinese males will have a major impact on the global burden of lung cancer in the 21st century, given the size of this population of smokers, which is more than 300 million. A unique feature of the epidemiology of lung cancer in China is the high lung cancer mortality rates among Chinese women despite the low prevalence of cigarette smoking. The inordinately high rates in women seem to be attributable to exposure to risk factors such as second-hand smoke exposure and indoor air pollution from cooking fumes.¹

Substantial geographic variation in lung cancer mortality rates has also been observed within countries, providing clues about the determinants of lung cancer. In the past, rates tended to be highest in urban areas, which led to conjecture that air pollution might be a cause of the lung cancer epidemic.³⁶ High rates in coastal areas in the United States from 1950 to 1969 were linked to asbestos exposure in shipyards.³⁷ Now lung cancer mortality rates among white males are highest in the South and lower in the Northeast, likely reflecting patterns of cigarette smoking.³⁸

LUNG CANCER BY HISTOLOGIC TYPE

Lung cancer manifests itself in multiple histologic types as classified by conventional light microscopy. The four major types, as traditionally identified by histologic appearance, include squamous cell carcinoma, adenocarcinoma, large

cell carcinoma, and small cell undifferentiated carcinoma; together these four types of lung cancer account for more than 90% of lung cancer cases in the United States.³⁹ These primary bronchogenic carcinomas are composed of a family of epithelial tumors that represent a subset of a larger collection of lung and pleural tumors classified by the *World Health Organization* (WHO) in 2004.⁴⁰ However, recent advances in molecular biology, surgery, and clinical medicine have rendered these traditional histologic classifications inadequate for optimal patient care. The need for more refined classifications was necessitated by several developments: (1) adenocarcinoma with *epidermal growth factor receptor* (EGFR) mutations was found to be sensitive to tyrosine kinase inhibitors, (2) eligibility for certain novel medications was limited to those with adenocarcinoma, and (3) *computed tomography* (CT) screening studies were detecting ground-glass infiltrative lesions that posed diagnostic challenges for both radiologists and pathologists. Consequently, the classification of adenocarcinoma was refined as part of a multidisciplinary, international effort to incorporate molecular and clinical parameters, define terms uniformly, and optimize relevance to patient care.⁴¹ The evidence-based recommendations created new adenocarcinoma subtypes according to prognostic criteria and molecular patterns, and discontinued the term “bronchioloalveolar carcinoma.” Reports have subsequently corroborated the new classification and documented its improved relevance to patient care.^{42–44} This topic is covered in detail in Chapters 14 and 53, but is included here because future research into the etiology of lung cancer would be strengthened by integrating these new lung cancer classification criteria.

Figure 52-3 Age-adjusted death rates per 100,000 population, male and female, 1986 to 1988. (Data from National Cancer Institute [NCI], Cancer Statistics Branch, and Division of Cancer Prevention and Control: *Cancer rates and risks*. Bethesda, MD: National Institutes of Health, 1996.)

Few links have been made between particular etiologic agents and the development of a particular histologic type of lung cancer. Cigarette smoking increases risk for all major histologic types.⁴⁵⁻⁴⁷ The dose-response relationship of increased lung cancer risk according to number of cigarettes smoked varies across the types, being steepest for small cell undifferentiated carcinoma.⁴⁵⁻⁴⁷ A few occupational exposures, such as chloromethyl ethers and radon, have been linked to small cell lung cancer.^{39,48}

In the United States, during the initial decades of the smoking-caused epidemic of lung cancer, the most frequent

type of lung cancer was squamous cell carcinoma, followed by small cell carcinoma. In the 1970s, a shift toward a predominance of adenocarcinoma was noted,^{39,49,50} and with the persistence of this trend, adenocarcinoma is now the most common histologic type.^{13,20} In U.S. men, the shift to adenocarcinoma developed in part because, whereas lung cancer incidence and mortality rates began to decline during the 1990s, the decline in lung cancer rates was more rapid for squamous cell and small cell carcinomas than for adenocarcinoma, which is just beginning to show a lower incidence rate (Fig. 52-4).¹³ In U.S. women, the

Figure 52-4 Cancer of the lung and bronchus: Surveillance, Epidemiology and End Results (SEER) incidence rates, by histologic type, sex, race, and ethnicity, all ages, 1973 to 1996. (Data from Wingo PA, Ries LA, Giovino GA, et al: Annual report to the nation on the status of cancer, 1973–1996, with a special section on lung cancer and tobacco smoking. *J Natl Cancer Inst* 91:675–690, 1999.)

increase in lung cancer incidence rates was more pronounced for adenocarcinoma than for any other cell type, perhaps because lung cancer rates increased most rapidly among U.S. women during the time period of changing histology.

Similar trends have been noted throughout the globe. Worldwide, adenocarcinoma tends to be the most common cell type seen in female lung cancer patients, accounting for approximately one-third of all lung cancer diagnoses in most regions.⁵¹ In males, squamous cell carcinoma is still the most common cell type in some geographic regions where the lung cancer epidemic has peaked, but trends indicate that the overall percentage of this cell type has fallen over time to 40% or less.

Hypotheses concerning the shift from squamous cell carcinoma to adenocarcinoma have focused on the potential role of changes in the characteristics of cigarettes and consequent changes in the doses and types of carcinogens inhaled.^{7,52,53} The resulting evidence from studies that have tested these hypotheses indicates that the trend of increasing rates of adenocarcinoma is primarily due to changes in cigarette smoking behavior and features of cigarettes (see later).^{54,55}

THE ETIOLOGY OF LUNG CANCER: OVERVIEW

Although the causes of lung cancer are almost exclusively environmental, there is likely substantial individual variation in susceptibility to respiratory carcinogens. For example, lung cancer develops in only a minority of smokers. The disease can be conceptualized as the consequence of the interrelationship between (1) exposure to

etiologic (or protective) agents and (2) individual susceptibility to these agents. Given lung cancer's multifactorial etiology, synergistic interactions among risk factors have substantial consequences for lung cancer risk. These interactions have typically been considered on an agent-by-agent basis, for example, as in studies of the synergistic effect of cigarette smoking on the lung cancer risk from asbestos exposure.⁶ Our emerging understanding of cancer genetics indicates the additional relevance of gene-environment interactions.

Given the many risk factors that have been identified for lung cancer, a practical question is: What is the relative contribution of these factors to the overall burden of lung cancer? In the United States, active smoking is estimated to be responsible for about 85% of lung cancer⁷; occupational exposures to carcinogens account for approximately 5% to 10%; radon causes 15% of lung cancer,⁴⁸ and outdoor air pollution perhaps 1% to 2%.⁵⁶ These known causes may not fully account for the development of lung cancer in never smokers, an important group for whom further epidemiologic research is needed.⁵⁷ Because these attributable risk estimates include joint contributions of risk factors, for example, smoking and occupation, the total percentage can exceed 100%.

ENVIRONMENTAL AND OCCUPATIONAL AGENTS

SMOKING (Chapter 46)

Overview

Cigarette smoking is by far the leading cause of lung cancer, accounting for approximately 80% to 90% of lung cancer

Table 52-2 Age-Specific Lung Cancer Mortality Rates (per 100,000) Among Men and Women 60 to 69 Years of Age by Smoking Levels in the American Cancer Society's Cancer Prevention Study II

Group	Never Smokers	SMOKED 20 CIGARETTES PER DAY FOR		SMOKED 40 CIGARETTES PER DAY FOR	
		30 Years	40 Years	30 Years	40 Years
Men	11.9	224.3	486.8	572.8	606.6
Women	9.8	200.8	264.4	257.7	552.8

In Burns DM, Garfinkel L, Samet JM, editors: *Changes in cigarette-related disease risks and their implication for prevention and control*. Bethesda, MD: U.S. Government Printing Office, 1997, pp 305–382.

cases in the United States⁷ and in other countries where cigarette smoking is common.⁴⁸ Compared with never smokers, current smokers have about a 25-fold increase in lung cancer risk, far higher than the risks for diseases associated with other environmental agents.⁵⁸ Cigar and pipe smoking are also established causes of lung cancer.⁵⁹ In general, lung cancer trends closely reflect patterns of smoking, but rates of lung cancer lag smoking rates by about 20 years. According to the Centers for Disease Control and Prevention, in the United States, 156,900 men and women die of smoking-related lung cancer each year.⁶⁰ Worldwide, 5.4 million people die of smoking-related lung cancer each year.⁶¹

Quantitative Risks

The risk of lung cancer among cigarette smokers increases with the duration of smoking and the number of cigarettes smoked per day (Table 52-2).⁶² In one widely cited analysis, Doll and Peto⁶³ proposed a quantitative model for lung cancer risk based on data from the cohort study of British physicians. This model predicted a stronger effect from the duration of smoking than from the amount smoked per day. Thus a tripling of the number of cigarettes smoked per day was estimated to triple the risk whereas a tripling of duration of smoking was estimated to increase the risk 100-fold.⁶⁴ These quantitative dimensions of the dose-response relationship between smoking and lung cancer have implications concerning the now widespread smoking among youths. Those starting at younger ages have a greater likelihood of becoming heavier smokers and remaining smokers.⁶⁵ The exponential effect of duration of smoking on lung cancer risk markedly increases the lifetime risk for those who become regular smokers in childhood.

Smoking Cessation

Cigarette smokers of any age can benefit from quitting smoking.^{58,66,67} Among those who quit smoking, the likelihood of developing lung cancer decreases when compared with those who continue to smoke^{7,58,67-69} (Table 52-3). As the period of abstinence from smoking cigarettes increases, the risk of lung cancer decreases.^{68,69} However, even for periods of abstinence of more than 40 years, the risk of lung cancer for former smokers remains elevated compared

Table 52-3 Risk of Lung Cancer Among Ex-Smokers Relative to Never Smokers According to Length of Time Since Smoking Cessation and Number of Cigarettes Formerly Smoked Among a Cohort of U.S. Veterans

Years Since Smoked	CIGARETTES SMOKED PER DAY				Total
	1–9	10–20	21–39	40	
<5	7.6*	12.5	20.6	26.9	16.1
5–9	3.6	5.1	11.5	13.6	7.8
10–19	2.2	4.3	6.8	7.8	5.1
20–29	1.7	3.3	3.4	5.9	3.3
30–39	0.5	2.1	2.8	4.5	2.0
≥40	1.1	1.6	1.8	2.3	1.5

*Relative risk compared with referent category of never smokers (=1). Adapted from Hrubec Z, McLaughlin JK: Former cigarette smoking and mortality among U.S. veterans: A 26-year follow-up, 1954–1980. Bethesda, MD, 1997, U.S. Government Printing Office, pp 501–530.

with that for never smokers (see Table 52-3). The benefits derived from smoking cessation also depend on the prior duration of smoking: for a given period of abstinence, the risk decreases with a decrease in the duration of previous smoking.⁶⁹

The Changing Cigarette and Expanding Marketplace

The composition and design of cigarettes has changed considerably since the 1950s. The marketplace has shifted from mainly unfiltered cigarettes to predominantly filtered cigarettes and to products that are labeled “light” or “mild.” In the mid-1960s, ventilation holes were added to the filter, which draw in air and dilute the inhaled smoke. However, whereas these holes effectively decrease the tar measured by the testing machines, smokers can readily block the holes with their fingers, thereby increasing their tar inhalation and exposure to carcinogens. Reconstituted tobacco, essentially reprocessed tobacco leaf wastes, has been used increasingly since the 1960s, and there have been changes to the cigarette paper and additives.⁷⁰ These changes in design and content may also have affected carcinogenicity.

Despite product marketing that would make these changes appear to be less harmful, the evidence indicates that, if anything, the changes in cigarettes have yielded greater—not lower—risks for lung cancer. A comparison of three U.S. cohorts, each comprised of more than 500,000 participants followed from 1959 to 1965, 1982 to 1988, and 2000 to 2010, provide very strong evidence to assess temporal trends in the association between cigarette smoking and lung cancer.⁵⁸ The relative risks of current smoking in relation to lung cancer mortality increased across these three time periods, a trend that was most pronounced in women among whom the relative risk increased across these three time periods from 2.7 to 12.7 to 25.7. In men, the relative risk increased and then plateaued, from 12.2 to 23.8 to 25. With respect to lung cancer risk, these data provide strong evidence that cigarettes have become more harmful rather than less harmful over time. These

findings are consistent with the conclusions of several expert panels that reviewed prior evidence.^{6,7,71,72}

During the past decade, the marketplace for tobacco products and devices that deliver nicotine has greatly expanded even as smoking bans have increasingly limited the locations where cigarette smoking is allowed.⁷³⁻⁷⁶ This diversification exists for both tobacco products and nontobacco products that deliver nicotine. In addition to the traditional smokeless tobacco products of loose leaf chewing tobacco and moist snuff, newer or more broadly marketed products include snus (a tobacco powder product packaged in a bag that is moister than snuff and does not require spitting) and dissolvable tobacco.⁷³ Furthermore, an increase in the prevalence of smoking roll-your-own cigarettes has been observed in the United States and elsewhere.^{77,78} The prevalence of smoking tobacco through a waterpipe, also referred to as “hookah,” has increased worldwide.^{76,79} Electronic cigarettes (or “e-cigarettes”) are non-tobacco-containing nicotine delivery devices that have experienced a rapid upsurge in use and are now marketed by the major U.S. tobacco companies.^{73,74,80,81}

Drawing upon past experience with the changing cigarette, it is clear that monitoring this expansion in products and how the products are used is not only critical to tobacco control but also directly relevant to the prevention of lung cancer. A product such as the e-cigarette that ostensibly decreases delivery of carcinogens to the lung would reduce the risk for development of lung cancer if current cigarette smokers switched from smoking cigarettes to exclusive use of the e-cigarette. In contrast, the risk for lung cancer could be increased if the e-cigarette maintained nicotine addiction and its users continued to smoke cigarettes as well in the increasingly common pattern of use of multiple products that deliver nicotine. Furthermore, these alternative products may serve as a gateway for youths to initiate smoking and thus start on a path that eventually leads to tobacco addiction. Questions such as these, along with the direct adverse health effects associated with use of these alternative products, are important lines of inquiry for future research.

Passive Smoking

Passive smokers inhale a complex mixture of smoke now widely referred to as “environmental tobacco smoke” or “secondhand smoke.” Passive smoking was first considered as a possible risk factor for lung cancer in 1981 when two studies were published that described increased lung cancer risk among never-smoking women who were married to smokers.^{82,83} Additional evidence rapidly accrued so that by 1986, two reports, from the National Research Council⁸⁴ and the 1986 Surgeon General’s Report,⁸⁵ both concluded that passive smoking causally increased risk for lung cancer. Estimates indicate that passive smoking accounts for about 3400 lung cancer deaths per year in the United States.⁸⁶

Since these conclusions were reached, numerous studies have been carried out to characterize further the association of passive smoking with lung cancer, while taking into account some of the limitations of earlier studies, particularly small sample sizes, exposure misclassification, and omission of some potential confounding factors.^{87,88} Various panels since 1986 have also concluded that passive smoking

increases lung cancer risk, including the International Agency for Research on Cancer,⁶ the California Environmental Protection Agency,⁸⁶ and once again, the U.S. Surgeon General.⁸

Passive smoking is more weakly associated with lung cancer than is active smoking, as expected given the lower doses of carcinogens received by the nonsmoker compared with the smoker. Marriage to a smoker is associated with about a 20% increase in risk⁸⁹ and exposure in the workplace is associated with between a 24% increase in risk up to a twofold increase at the highest levels of exposure.⁹⁰ In general, the risk of lung cancer increases as the exposure to secondhand smoke increases.⁹⁰

DIET

The possible role of diet in modifying the risk for lung cancer has been the focus of intensive investigation, driven initially by the rationale that specific micronutrients might have anticarcinogenic activity. The most thoroughly investigated dietary factors are also those that at present appear to have the greatest implications for prevention: fruits, vegetables, and specific antioxidant micronutrients that are commonly found in fruits and vegetables.

The results of case-control and prospective cohort studies have tended to show that individuals with high dietary intake of fruits or vegetables have a lower risk for lung cancer than those with a low intake.⁹¹ To understand the basis of this protective association, researchers have grouped fruits and vegetables into classes and examined them individually in relation to lung cancer risk. For example, tomatoes⁹¹ and cruciferous vegetables^{91,92} have been associated with a reduced risk for lung cancer in a number of studies. These food-based analyses can help clarify whether protection arises from the complex mixture that composes fruits and vegetables or from specific biochemical constituents present in particular fruits and vegetables.

Fruits and vegetables are the major dietary source of antioxidant micronutrients. Much of the research on diet and lung cancer has been motivated by the hypothesis that diets high in antioxidant micronutrients may protect against oxidative DNA damage and thereby protect against cancer. For example, this was one of the hypothesized roles for β -carotene,⁹³ the focus of now controversial clinical trials. Two different strategies are used to evaluate the relationship of micronutrients to lung cancer risk in observational epidemiologic studies: (1) estimating micronutrient intake from food-frequency questionnaires and (2) measuring serum concentrations of micronutrients. Prospective studies of both dietary intake⁹⁴ and prediagnostic blood concentrations⁹⁴ suggest that carotenoids are inversely associated with lung cancer risk.

The protective association predicted between β -carotene and lung cancer on the basis of these observational epidemiologic studies was not confirmed in three randomized, double-blind, placebo-controlled chemoprevention trials.⁹⁵⁻⁹⁷ In fact, two of these studies with participants at high risk for lung cancer (heavy smokers and asbestos-exposed workers) were stopped early because significantly increased risk for lung cancer was observed in the β -carotene group compared with the placebo group.^{96,97}

The results of the randomized chemoprevention trials stand in sharp contrast to the considerable observational epidemiologic evidence favoring a protective association. Among the potential explanations for the contradictory findings are that the randomized trials used relatively high doses of β -carotene and that the observational epidemiologic studies may have been flawed by uncontrolled confounding or selection bias.⁹⁴ Because of the powerful role of smoking as a cause of lung cancer, disentangling the effects of other lifestyle-related factors, such as diet, from the effect of smoking may be particularly difficult. Further complicating the assessment of protection by dietary factors is the narrow range of likely effects, much smaller than the effect of smoking, and the unavoidable problem of measurement error, that is, the inevitable inaccuracy in estimating usual dietary consumption of particular foods or groups of foods.

Studies of fruits, vegetables, and micronutrients have been the centerpiece of studies of diet and lung cancer, but other factors have also been investigated. For example, the results of a meta-analysis showed alcohol drinking in the highest consumption categories was associated with increased risk for lung cancer.⁹⁸ In addition, anthropometric measures have been studied, indicating a tendency for persons with lower body mass index to have increased lung cancer risk relative to heavier persons.⁹¹ However, both alcohol drinking and low body mass index may be difficult to separate from the concomitant effects of smoking. At present, when considering the possible relationships between lung cancer and factors such as alcohol drinking and lower body mass index, residual confounding by cigarette smoking cannot be dismissed as a possible explanation.

ENVIRONMENTAL EXPOSURES

Occupational Exposures

Lung cancer has been found to be associated causally with many workplace exposures, including arsenic, beryllium, cadmium, chromium, and nickel in addition to those described later.^{99,100} Occupational exposure to lung carcinogens have been estimated by case-control studies to account for 9% to 15% of lung cancer cases.¹⁰¹ As lung carcinogens have been identified in the workplace and regulations established to prevent workers from being exposed, this proportion has been decreasing over time. Cigarette smoking also potentiates the effect of some of the known occupational lung carcinogens.⁶

Asbestos

Asbestos, a well-established occupational carcinogen,^{99,100} refers to several forms of fibrous, natural silicate minerals.¹⁰² The epidemiologic evidence that asbestos causes lung cancer dates to the 1950s. In a retrospective cohort study published in 1955, Doll observed that asbestos textile workers at a factory in the United Kingdom had a ten-fold elevation in lung cancer risk and that the risk was most heavily concentrated during the timeframe before regulations were implemented to limit asbestos dust in factories.¹⁰³ A sevenfold excess of lung cancer was subsequently observed among insulation workers in the United States,^{104,105} with peak incidence at 30 to 35 years after the initial exposure to asbestos.¹⁰⁶ The risk of lung cancer has been noted to increase with increased exposure to asbes-

tos¹⁰⁷ and to be associated with each of the principal commercial forms of asbestos.¹⁰⁸ Whether asbestos acts directly as a carcinogen or indirectly, for example, by causing chronic inflammation that eventually leads to cancer, remains controversial.¹⁰⁹⁻¹¹¹ For the mechanism of asbestos-induced lung cancer, two competing hypotheses have been posed: (1) lung cancer arises as a consequence of the asbestos-induced lung disease asbestosis and (2) lung cancer arises directly from asbestos exposure while the asbestosis merely serves as a marker of asbestos dose. Regardless of mechanism, asbestos is a known lung carcinogen and the number of exposed workers is increasing in South America, Asia, and the former Soviet Union.¹⁰⁰

Asbestos and cigarette smoking are both independent causes of lung cancer but, in combination, they act synergistically to increase risk. Uncertainty remains as to the precise quantitative characterization of this synergy, reflecting limitations of the available data⁶ and lack of understanding of the underlying mechanisms.¹¹² Nonetheless, the risk of the combined exposure is much higher than would be expected if one merely added the risks together, showing a strong interaction between the two. In fact, the risks are approximately multiplicative. A person who smokes and has been exposed to asbestos has a greater than 50-fold elevated risk for lung cancer than does a nonsmoker with no asbestos exposure, and a much higher risk than a person exposed to cigarette smoke alone (relative risk, 10.9) or to asbestos alone (relative risk, 5.2) (Table 52-4).¹¹³

Radiation

Epidemiologic studies of populations exposed to high doses of radiation show that lung cancer is causally associated with exposure to ionizing radiation. Two types of radiation, classified by the rate of energy transfer to the tissue, are relevant to lung cancer: high *linear energy transfer* (LET) radiation (e.g., neutrons and radon) and low-LET radiation (e.g., x-rays and γ -rays). High-LET radiation produces ionization of relatively higher density in tissues than low-LET radiation, so in equivalent doses, more biologic damage is produced by high-LET than low-LET radiation.¹¹⁴ For both types of radiation, the epidemiologic evidence initially came

Table 52-4 Relationship Between Cigarette Smoking and Asbestos Exposure on Lung Cancer Mortality Risk

SMOKING	MORTALITY RATES		DIFFERENCE IN RATES		RATIO OF RATES	
	ASBESTOS		ASBESTOS		ASBESTOS	
	No	Yes	No	Yes	No	Yes
No	11.3*	58.4	0	47.1	1.0	5.2
Yes	122.6	601.6	111.3	590.3†	10.9	53.2‡

*Mortality rate per 100,000.
†Difference in rates compared to no smoking/no asbestos exposure; if there were no interaction of asbestos and smoking, the expected rate of lung cancer in those exposed to both would be the sum of each alone (47.1 + 111.3 = 158.4). The actual value of 590.3 greatly exceeds 158.4, providing evidence of a strong interaction between smoking and asbestos.
‡Ratio of rates compared to no smoking/no asbestos exposure; the expected value if risks were multiplicative would be the multiple of the rates, 5.2 \times 10.9 = 56.7, close to the actual value of 53.2.
Adapted from Hammond EC, Selikoff IJ, Seidman H: Asbestos exposure, cigarette smoking and death rates. *Ann N Y Acad Sci* 330:473-490, 1979.

primarily from cohorts exposed at levels substantially greater than those experienced by the general population and risk assessment methods were used to estimate risks to the general population. More recently, studies have generated evidence concerning exposure levels experienced directly by the general population.

High-LET Radiation: Radon. Radon is an inert gas produced naturally from radium in the decay series of uranium. Two of the radon decay products emit alpha particles that can, consequent to high energy and mass, cause damage to the DNA of cells of the respiratory epithelium. Epidemiologic studies of underground miners of uranium and other ores have established exposure to radon daughters as a cause of lung cancer.^{48,115} In the underground miners exposed to radon in past centuries, very high lung cancer risks were observed; in the miners in more contemporary workplaces, the observed risks have been much less as exposure concentrations have been better controlled, but still show clear evidence of existing cancer risk.⁴⁸ Cigarette smoking and radon decay products synergistically influence lung cancer risk, for example, in a manner that is greater than simply adding the risks of each together.⁴⁸ For this reason, the bulk of the lung cancer burden caused by radon exposure in the general population is concentrated within cigarette smokers.¹¹⁶

Radon is of broader societal interest because it is a ubiquitous air pollutant that enters buildings from the underlying soil. On average, indoor exposures to radon for the general population are much less than for occupational groups such as uranium miners; but the results of case-control studies of indoor radon exposure have documented that residential exposure to radon in indoor air is significantly associated with increased lung cancer risk.^{117,118}

The assumptions made by the Environmental Protection Agency and the Biological Effects of Ionizing Radiation VI Committee of the National Research Council have led to estimates that approximately 15,000 to 20,000 lung cancer deaths per year in the United States are caused by radon.¹¹⁹ In the United States, the Environmental Protection Agency has called for testing of all residences and mitigation when guideline values are exceeded.

Low-LET Radiation: X-Rays and γ -Rays. Earlier epidemiologic data relating low-LET radiation to lung cancer stem from three principal populations¹²⁰: the atomic bomb survivors in Japan, patients with diseases such as ankylosing spondylitis or tuberculosis who received multiple radiation treatments, and occupational groups in professions exposed to radiation. The single, high-dose exposure of the atomic bomb survivors was associated with significant lung cancer risk.¹²¹ Regardless of age at the time of the blast, the excess of lung cancer appeared when the survivors reached the older ages at which cancer usually develops.¹²² Quantitative risk models are available that describe how risk increases with radiation dose.¹²⁰

Over the past several decades, medical radiation has replaced radon as the leading contributor to the population's radiation exposure. In general, a substantial proportion of the U.S. population is now exposed to ionizing radiation from medical diagnostics, particularly from CT scans. The exposure is of sufficient magnitude to be of

concern as a cause of increased population risk for cancer.¹²³⁻¹²⁵ The findings from the National Lung Screening Trial showed that *low-dose spiral CT* (LDCT) screening significantly reduced lung cancer mortality among those at high risk for lung cancer defined by age (55 to 74 years) and smoking history (≥ 30 pack-year smoking history).¹²⁶ Based on the findings of the National Lung Screening Trial, the U.S. Preventive Services Task Force recommends annual screening in the high-risk group as defined in the National Lung Screening Trial.¹²⁷ LDCT screening will result in increased exposure of smokers to ionizing radiation. In making their recommendation in support of LDCT screening, the U.S. Preventive Services Task Force acknowledged that there is uncertainty about the magnitude of the radiation-associated risks. Characterizing the magnitude of risks associated with LDCT screening is an important future priority, because risk models that have attempted to quantify these risks indicate that they are not trivial.^{128,129}

AIR POLLUTION

During a typical day, the average adult inhales about 10,000 L of air.¹³⁰ Consequently, even the carcinogens present in the air at low concentrations are of concern as a risk factor for lung cancer.

Atmospheric Air Pollution

Outdoor air can contain a number of hazardous agents. Many of these are generated by the combustion of fossil fuels, including carcinogens such as polycyclic aromatic hydrocarbons and metals such as arsenic, nickel, and chromium.¹⁰⁰ Depending on the pollution sources, the constituents of "air pollution" vary by locale and over time.

Particulate matter, which has multiple sources in urban air, has been studied as a potential lung cancer risk factor. In a study in six U.S. cities, a 40% increase in lung cancer risk was found in residents in the city with the highest concentration of fine particles in the atmosphere compared to the city with the lowest concentration.¹³¹ The data from the American Cancer Society's Cancer Prevention Study II showed that each 10 g/m³ increase in concentration of fine particles carried an increased lung cancer risk of 14%.¹³² A European study of more than 300,000 individuals from nine countries observed that the risk of lung cancer increased significantly as the concentration of particulate matter increased.¹³³ Further evidence indicating an association between constituents of ambient air pollution and increased lung cancer mortality continues to accrue, with reports from Japan,¹³⁴ China,¹³⁵ and New Zealand¹³⁶ documenting increased risks with measures of particulate matter, sulfur dioxide, and nitrogen dioxide. The existing evidence base indicates that atmospheric air pollution is a risk factor for lung cancer. The evidence is strongest for particulate matter, but may also extend to other constituents of polluted air. A large number of people who live in cities are exposed to outdoor air pollution, so even a small effect is of public health importance.

Indoor Air Pollution

Indoor air pollution arises from pollutants that enter from the outside as well as those that originate indoors from tobacco smoking, building materials, soil gases, household

products, and combustion from heating and cooking.¹³⁷ In the more developed countries, two of the most important indoor pollutants that influence lung cancer risk in never smokers are passive smoking⁸⁵ and radon.¹¹⁵ In the developing world, the major source of indoor air contamination results from the use of unprocessed solid fuels, notably coal (a fossil fuel) but also biomass fuels, for cooking and space heating.¹³⁸ Mumford and coworkers¹³⁹ inferred that smoky coal was a major determinant of the geographic distribution of lung cancer in Xuan Wei, China, a finding corroborated by an animal model.¹⁴⁰ Evidence supporting a causal association was subsequently strengthened by studies documenting that switching from use of unvented fire pits to stoves with chimneys¹⁴¹ or to portable stoves¹⁴² cut the lung cancer risk in half.

Indoor burning of biomass, such as wood, is associated with lung cancer risk, but the association is weaker than for fossil fuel burning. This was illustrated in a pooled analysis of seven case-control studies, in which the risk of lung cancer was strongest for indoor burning of coal in Asia (*odds ratio* [OR] 4.9; 95% *confidence interval* [CI] 3.7 to 6.5) and weaker—but still statistically significant—for indoor burning of wood in Europe and North America (OR 1.2; 95% CI 1.1 to 1.4).¹⁴³ These findings were corroborated in a meta-analysis of published studies.¹⁴⁴ Indoor burning of solid fuel is a major cause of lung cancer in China and one that is preventable.³⁵ Based on statistical models, projections indicate that reductions in the indoor burning of solid fuel would substantially reduce lung cancer deaths.¹⁴⁵

HOST FACTORS

OVERVIEW

The long-standing interest in genetic susceptibility to lung cancer has recently intensified. Environmental agents, even cigarette smoking, cause lung cancer in only a minority of exposed persons, leading to the hypothesis that susceptibility is inherently determined. Studies showing that a family history of lung cancer predicts increased risk further support a genetic basis for lung cancer susceptibility. This long-postulated hypothesis is now being actively addressed using the approach of molecular epidemiology. Aspects of genetic susceptibility have been reviewed.¹⁴⁶

A positive family history of lung cancer is a clinically useful risk indicator. In a meta-analysis, a positive family history of lung cancer was associated with a 1.7-fold increased risk of lung cancer (95% CI 1.6 to 1.9), an association that was only slightly weaker among nonsmokers (OR 1.4; 95% CI 1.2 to 1.7).¹⁴⁷ A positive family history of lung cancer in two or more relatives was associated with substantially greater risk (OR 3.60; 95% CI 1.6 to 8.3).¹⁴⁷ These findings were reinforced by the results of a pooled analysis in which a positive history of lung cancer in a first-degree relative was associated with 1.5-fold increased risk for lung cancer (95% CI 1.4 to 1.6) with a significant but slightly weaker association among never smokers (OR 1.3; 95% CI 1.03 to 1.5).¹⁴⁸ The familial risk for lung cancer is approximately equal to the associations observed for prostate, breast, and colon cancers, which have a known genetic component.¹⁴⁹

In a large study in Louisiana, segregation analysis suggested that lung cancer inheritance was consistent with a mendelian codominant autosomal gene determining early onset of disease.¹⁵⁰ Conversely, the largest study of lung cancer in twins reported to date did not provide evidence indicating a genetic basis for susceptibility.¹⁵¹

In a genetic epidemiology study of lung cancer in nonsmokers in Detroit, Schwartz, Yang, and colleagues^{152,153} explored familial risk for lung cancer. In nonsmokers, Schwartz and associates¹⁵² found an association between risk and a history of lung cancer in a first-degree relative (OR 1.4; 95% CI 0.8 to 2.5). The association was much stronger in those aged 40 to 59 years at diagnosis than in older persons, suggesting that genetic factors may be more important at younger ages. This general finding was confirmed by a subsequent complex segregation analysis of the same data.¹⁵³

RESEARCH FINDINGS ON THE GENETIC BASIS OF LUNG CANCER (Chapter 51)

Studies to investigate genotypic variation in relation to lung cancer risk have evolved rapidly since the 1980s. Initially, the research paradigm relied on identifying and studying candidate genes with functional polymorphisms hypothesized to be related to lung carcinogenesis, such as carcinogen detoxification or DNA repair genes. The sequencing of the human genome and the development of high-throughput assays that enable increasingly larger numbers of single nucleotide polymorphisms to be measured in larger studies has led to the new paradigm of *genome-wide association studies* (GWAS). In contrast to the candidate gene approach, which is based on deduction, the GWAS approach is inherently inductive. GWAS studies entail measuring as many single nucleotide polymorphisms as possible—currently more than a million—to determine which regions of the genome are associated with lung cancer risk. Because there is no need to have prior knowledge of the genetic function of the region under consideration, the GWAS approach is exploratory and studies using this approach must be specifically designed to guard against false-positive findings and overfitting. As such, sample sizes tend to be large.

Of primary interest in studies using the candidate gene approach are genes that encode for enzymes in carcinogen metabolism and DNA repair pathways and that are polymorphic in humans. Selected examples are described later. The metabolism of toxic agents, including carcinogens, generally proceeds through two phases.¹⁵⁴

In phase 1, unreactive nonpolar compounds are converted, usually by oxidative reactions, to highly reactive intermediates. Many carcinogenic compounds in tobacco smoke (e.g., polycyclic aromatic hydrocarbons) undergo metabolic activation by phase 1 enzymes of the cytochrome P-450 system to form reactive intermediates that bind to DNA and cause genetic injury. For example, for the gene that encodes one of the P-450 enzymes, *CYP1A1*, the current evidence suggests that two specific polymorphisms, in *MspI*¹⁵⁵ and in exon 7,¹⁵⁶ are associated with increased lung cancer risk.

In phase 2, these intermediates are joined with conjugating molecules to form complexes, which are usually less reactive and more easily excreted. However, the intermediate metabolite may react with other cellular components,

such as DNA, before it is conjugated. This binding to DNA may be the first step in the initiation of the carcinogenic process.¹⁵⁴ One of the phase 2 enzymes, glutathione S-transferase, detoxifies reactive metabolites of polycyclic aromatic hydrocarbons. The results of a meta-analysis indicated that those with the GSTM1-null had a slightly higher lung cancer risk than the GSTM1-present genotype, but a pooled analysis of data from 21 case-control studies did not indicate that this susceptibility was stronger among cigarette smokers than among nonsmokers.¹⁵⁷

Another pathway where genetic variation has been of hypothesized importance in determining susceptibility to lung cancer is DNA repair.^{158,159} One of the most extensively studied DNA repair genes to date is the nucleotide excision repair gene *XPB*.^{160,161} The evidence has not yet revealed a consistent pattern of associations for lung cancer and any specific polymorphism. In summary, the candidate gene approach has not yielded clear-cut associations with lung cancer risk.

GWAS are now being reported, with encouraging results. The results of four separate studies, all published in 2008, have been remarkably consistent in identifying a region on the long arm of chromosome 15 (15q24-25.1).¹⁶²⁻¹⁶⁵ For example, subjects with at least one variant allele of a specific single nucleotide polymorphism in this region (rs8034191), present in approximately one-third of the study population, were at 1.3 times greater risk for lung cancer than those with the wild-type allele.¹⁶³⁻¹⁶⁵ This region of chromosome 15 contains 3 identified coding areas for nicotine acetylcholine receptors. Nicotine acetylcholine receptors mediate an individual's sensitivity to nicotine, suggesting that those with these variant alleles may be at an increased risk for nicotine addiction and hence tobacco carcinogen exposure. A second region on the short arm of chromosome 6 (6p21) was reported to be involved in cancer risk in two European studies in 2008.^{163,166} This locus, which maps to the major histocompatibility complex, was also associated with increased lung cancer susceptibility and poor survival in an Asian population with advanced non-small cell lung cancer.¹⁶⁷ A third gene region identified another susceptibility locus on the short arm of chromosome 5 that contains two genes known to be biologically relevant in lung cancer, *TERT* (human telomerase reverse transcriptase) and *CLPTMIL* (cleft lip and palate transmembrane-1-like).¹⁶⁸ Despite the identification of these three susceptibility loci, cumulatively they represent less than 10% of the familial lung cancer risk. It is possible that rare variants may explain some of the residual familial lung cancer risk.

With application of the new and powerful tools of modern molecular biology, research findings are now characterizing the changes in cells that are caused by exposure to tobacco smoke and providing a framework for understanding the genetic and epigenetic basis of lung cancer risk. A rapidly expanding literature, termed "molecular epidemiology," is based both on laboratory and on observational data addressing dosimetry and metabolism of tobacco carcinogens at the cellular and molecular levels. This literature also analyzes the resulting patterns of genetic and epigenetic changes in the smoking-related cancers that develop as well as the "field" changes in the tissues surrounding those cancers, which also have genetic and epigenetic changes

caused by cigarette smoking. This literature has necessarily become more sophisticated in its description of the changes in cells induced by tobacco carcinogens as being genetic or epigenetic; DNA, RNA, or protein-based; and, more recently, reflective of the metabolic state of the cell.

As part of the Cancer Genome Atlas Project, the genomic and epigenomic profiles of 178 lung squamous cell carcinomas were characterized.¹⁶⁹ The data showed complex genomic alterations, with hundreds of exonic mutations, genomic rearrangements, and copy number alterations per tumor, in addition to many correlations between genomic and epigenomic aberrations. Common abnormalities in p53 and several cell cycle, oxidative stress, and apoptotic signaling pathways suggest a common mechanism for this cancer.

The understanding of the epigenetic changes that may be involved in the causal pathway to lung cancer is advancing rapidly. Methylation of cytosine in the DNA, leading to hypermethylation of promoter regions is important in regulating biochemical pathways and is a frequent alteration in most types of cancers, including lung cancer.¹⁷⁰ Promoter regions of many human genes have loci rich in CpG dinucleotides, regions referred to as CpG islands.^{170,171} Comprehensive genome-wide searches have identified numerous CpG island genes epigenetically silenced by DNA methylation that are able to distinguish neoplastic from nonneoplastic tissue. Cells with abnormal methylation of genes have been detected in sputum of subjects before their diagnosis of lung cancer, suggesting that hypermethylation could be a useful marker for early detection.^{172,173}

In a general formulation of determinants of cancer risk, the risk depends on carcinogen exposure as well as the factors that determine host susceptibility, including genetic predisposition.¹⁷⁴ Central to the molecular epidemiology approach are biomarkers, measures of indicators of exposure and dose, susceptibility, and response in biologic materials, including tissue samples, blood, urine, and saliva.¹⁷⁵ As research evolves within this paradigm, a more complete biologic understanding of the specific events underlying the multistage model, originally proposed on a conceptual basis, can be anticipated.

This framework indicates multiple points where genetically determined host characteristics might be important: carcinogen metabolism and activation, DNA repair, and cell cycle control/apoptotic response. There is a rapidly expanding literature on the molecular and cellular basis of lung cancer.¹⁴⁶ The evidence has expanded and deepened our understanding of how smoking injures cells and causes cancer, and indicates potential approaches to identifying high-risk individuals and molecular screening.

PRESENCE OF HUMAN IMMUNODEFICIENCY VIRUS

As the population of patients infected with *human immunodeficiency virus* (HIV) has aged, due to improved survival from highly active antiretroviral therapy, evidence from case reports,¹⁷⁶ patient series,¹⁷⁷ and observational studies¹⁷⁸⁻¹⁸⁰ has indicated that HIV-positive individuals have an increased risk for lung cancer. Best estimates from the cumulative data in observational cohorts and clinical registries suggest that HIV infection increases lung cancer risk at least 2.5-fold compared with risk in the

general population, independent of smoking status.¹⁸⁸ Consequently, lung cancer is now the most common and most fatal non-acquired immunodeficiency syndrome-associated malignancy in the HIV-positive population, accounting for 16% of deaths among all HIV patients.¹⁸¹

Some aspects of lung cancer in HIV-positive patients follow patterns observed in the general population. This includes the predominance of non-small cell lung cancer,^{182,183} with adenocarcinoma and squamous cell carcinoma as the two most common cell types^{180,182,184} and the presentation with advanced stage lung cancer, with only 10% to 15% of HIV-infected patients with diagnosed lung cancer amenable to curative resection.¹⁷⁸ However, other characteristics of this population are representative of the HIV-positive population. For example, the preponderance of HIV-positive patients with lung cancer are males,¹⁸² consistent with the higher prevalence of HIV infection in men than in women. Interestingly, lung cancer is diagnosed in HIV-positive individuals at younger ages than the norm, perhaps indicative of enhanced susceptibility to lung cancer or perhaps just due to the younger age of HIV-positive individuals.^{180,185} Remarkably, in the United States, approximately 80% of HIV-infected individuals with lung cancer are African Americans in some studies,¹⁷⁸ despite African Americans comprising only 12% of the general population and 46% of the HIV-infected population.¹⁸⁶

Even though HIV-positive individuals have an increased lung cancer risk above and beyond that due to cigarette smoking, the primary lung cancer risk factor in HIV-infected people, as in the general population, is cigarette smoking. In fact, in most studies, there are few HIV-positive lung cancer patients who are not also cigarette smokers. Despite the high risk for lung cancer in HIV-infected people, the cumulative duration of smoking exposure for HIV-infected lung cancer patients, for example, is less than in the general population,^{178,185} probably due to their younger age. This is consistent with the possibility that HIV infection enhances susceptibility to smoking-caused lung cancer, which is one of several hypotheses to explain why there is an excess lung cancer risk in HIV-positive individuals. The elevated lung cancer risk could also simply be due to a higher prevalence of cigarette smoking in HIV-positive individuals.^{182,187} Alternatively, HIV may itself contribute to lung carcinogenesis.¹⁸⁸ If so, potential explanations for the increased lung cancer risk could include (1) a direct carcinogenic effect of HIV, (2) a defective immune surveillance, and (3) inflammation due to recurrent opportunistic infections and parenchymal lung injury leading to inflammatory foci and scar carcinomas. Whereas recent evidence supports the notion that immunosuppression increases the risk for lung cancer development,¹⁸⁸ most HIV-infected lung cancer patients have only moderate immunosuppression¹⁷⁸ and other measures of immunocompetence such as CD4 count and HIV viral load do not seem to be strongly related to increased lung cancer risk.¹⁷⁹ Increased immunodeficiency in these patients, however, adversely affects response to treatment, because of an inability to tolerate cytotoxic therapy¹⁸⁹ as well as a reduced long-term survival after surgery.¹⁹⁰

Older age and more extensive histories of cigarette smoking are strongly associated with increased lung cancer risk, so as the population of HIV-infected individuals ages, the combined effect of age, the high prevalence of smoking,

and the excess lung cancer risk in this population will make this a very high-risk subgroup of the general population. Because of the high risk for lung cancer in HIV-infected individuals who are 55 years of age or older and have a history of cigarette smoking, it will be important to target this subgroup with smoking cessation interventions for primary prevention and with LDCT for early detection.

PRESENCE OF ACQUIRED LUNG DISEASE

In addition to hereditary factors, increased susceptibility to lung cancer may result from underlying lung disease. Such acquired lung diseases assume two major forms: (1) airway disorders that obstruct airflow, such as *chronic obstructive pulmonary disease* (COPD), and (2) fibrotic disorders that restrict lung capacity, such as pneumoconiosis.¹⁹¹

A substantial body of evidence suggests that COPD or impaired lung function is associated with the development of lung cancer.¹⁹² However, because cigarette smoking is the principal cause of both COPD¹⁹³ and lung cancer, statistical adjustment procedures that “remove” the effect of cigarette smoking may not be well founded. For example, the presence of COPD may indicate that the affected individual has received a greater dose of tobacco carcinogens than the typical unaffected individual. Alternatively, cigarette smoke may induce inflammation that can contribute both to COPD and to lung cancer.¹⁹⁴ Regardless of the mechanism, the presence of COPD is a clinically useful risk indicator.

Clarifying the possible relationship between pneumoconioses and lung cancer poses particularly vexing challenges. Even for asbestos exposure, which is clearly established as a potent cause of lung cancer,¹⁰⁸ whether lung cancer results from asbestos per se or from asbestosis remains unresolved (see earlier). For other mineral fibers, the evidence is even more uncertain.¹⁹⁵ For example, determining whether silica exposure or silicosis mediates the increased lung cancer risk in silica-exposed persons has proved difficult.^{196,197} It is recognized that the presence of silicosis is associated with an increased risk for lung cancer,¹⁹⁸ but understanding the basis of this association will entail isolating the independent effects of silica exposure and lung fibrosis while controlling for exposure to smoking and other lung carcinogens.¹⁹⁵

Such differences in the pattern of associations between pneumoconioses and lung cancer emphasize that “fibrosis” is not a homogeneous exposure but is dependent upon the properties of the specific mineral fiber or other environmental agent. Properties of the agent, such as its size, shape, and durability, and the effects of other exposures such as cigarette smoking are important considerations in assessing its potential harmfulness.¹⁹⁹

GENDER

The hypothesis has been advanced that females may have a greater lung cancer risk than males at the same level of smoking.^{200,201} However, direct tests of this hypothesis suggest it is not correct, because the results of studies that have compared the relative risk estimates for men and women for a specific degree of smoking history demonstrate very similar risks.^{58,202} In fact, as shown in the results

summarized in Table 52-2, women may even show a substantially lower risk for lung cancer than men for a specific smoking history. Some have hypothesized that women may have a lower lung cancer risk because men have higher exposures to other environmental lung carcinogens, such as occupational exposures, that synergistically interact with cigarette smoking. In another study of more than 950,000 individuals in the United States from 2000 to 2010, the relative risks of dying of lung cancer in current smokers compared with never smokers were nearly identical in women (relative risk 26) and men (relative risk 25).⁵⁸ Thus, for the same amount of smoking, women would appear to have the same or lower risk of lung cancer than men but not a higher risk.

However, interesting differences in characteristics of lung cancer between men and women have been noted.²⁰³ First, women with lung cancer have a better prognosis than men. Second, and somewhat in contrast with this notion, estrogen may enhance lung cancer risk. For example, a significantly increased risk of lung cancer (relative risk 1.4; 95% CI 1.03 to 1.8) was observed for hormonal therapy with estrogen plus progestin formulations in a meta-analysis of data from two large-scale randomized controlled trials.²⁰⁴ In addition, results of studies published after the meta-analysis reinforced the notion that hormonal therapy with estrogen plus progestin formulations may increase lung cancer risk.^{205,206} Third, some clear gender differences have become apparent in never smokers. Among never smokers, women have higher lung cancer incidence rates than men. Among never smokers in whom lung cancer develops, women have a higher percentage of adenocarcinomas than men and, in the subjects with adenocarcinomas, women have a higher prevalence of *EGFR* mutations than men. Observations such as these hint that distinct gender differences in lung carcinogenesis may exist that could potentially be clinically important.

FUTURE DIRECTIONS

In developing lung cancer prevention strategies, certain groups warrant particular attention. Steps need to be taken toward the goal of reducing the very high lung cancer incidence rates in African American men.²⁰⁷ Lung cancer is also a major women's health issue. Owing to historical cigarette smoking patterns, the epidemic of lung cancer started later in women than in men but, in contrast to the situation in men, lung cancer incidence rates in women are just now starting to decrease.²⁰⁸ Even though lung cancer remains a critical public health problem, the decrease in the overall lung cancer burden now seen in the United States, as in much of the developed world, reflects the successes of preventive strategies. A critical global priority is to prevent the uptake of cigarette smoking in developing countries where smoking prevalence is still low.

A consideration of the epidemiology of lung cancer consistently reinforces one major theme: the pandemic of lung

cancer is a consequence of the tragic and widespread addiction to cigarettes throughout the world. Curtailing the pandemic of lung cancer will require preventing youths from starting to smoke cigarettes and effectively promoting smoking cessation among addicted smokers. The rapidly expanding marketplace for tobacco products and nicotine-delivery devices and the shift toward patterns of mixed-use in younger smokers will require surveillance to characterize the prevalence of use and etiologic research to determine the net impact of the real-world use of these products.

Key Points

- In the United States, lung cancer remains the leading cause of cancer death in both men and women.
- The predominant cause of lung cancer is exposure to tobacco smoke, with active smoking causing most cases but passive smoking also contributing to the lung cancer burden.
- The reductions in smoking prevalence in men in the late 1960s through the 1980s will continue to drive lung cancer mortality rates downward during the first portion of the 21st century.
- Fortunately, exposures to major occupational respiratory carcinogens have largely been controlled, but the population is still exposed to environmental causes of lung cancer, including radon, the second leading cause of lung cancer death.
- Lung cancer is significantly more likely to develop in individuals infected with HIV than in uninfected individuals; the mechanisms underlying this association are not yet clearly established.
- Gender similarities and differences exist in lung cancer. The most important fact is that, among smokers, a similar smoking history results in similar lung cancer risk for women and men. Among never smokers, compared to men, women have a higher overall incidence of lung cancer, particularly of adenocarcinoma with epidermal growth factor receptor mutations.

INTRODUCTION

Lung cancer is the most common cause of cancer deaths worldwide. In the United States, lung cancer accounted for more than 250,000 cases of cancer and greater than 150,000 deaths from cancer in 2013.¹ Chapter 52 is dedicated to the epidemiology of lung cancer but some of the information found therein is worth repeating. For example, the number of lung cancer deaths each year exceeds the number of cancer deaths from breast, colon, and prostate cancer combined. A common misconception among the general public is that breast cancer accounts for more cancer deaths in women. However, lung cancer is now the greatest cancer killer of women and will account for 25% of cancer-related deaths among women in the United States. Particularly alarming is the fact that young women are in the fastest rising demographic of new cigarette smokers in the United States. Many have clearly made the association between weight control and cigarette smoking. This will have effects on the prevalence of lung cancer in the decades to come.

One of the more disturbing trends in lung cancer is the explosion in rates of lung cancer in countries of the developing world. In 1985, it was estimated that there were 921,000 lung cancer deaths worldwide—an increase of 17% from 1980.² In 2011, lung cancer accounted for 13% of cases (1.6 million) and 18% of deaths (1.4 million) worldwide.¹ The International Agency for Research on Cancer in France found that the rates of lung cancer in Africa in the early 1990s were similar to those in the United States in the 1930s, at about 5 per 100,000. By 1999, the rate of lung cancer in males in developing countries was 14 in 100,000 and on the rise, compared with a rate of 71 in 100,000 in developed countries, which continues to decline. These rates may actually be underestimates of the true

rates of lung cancer, because many cases may go undiagnosed or underreported in areas where health care is not readily available.² The seriousness of this problem is exemplified in China, where it is estimated that nearly 800,000 Chinese men died of lung cancer in 1998.² It remains imperative that the medical community devotes much of its educational efforts and resources to the elimination of cigarette smoking worldwide, which would nearly eliminate the development of lung cancer (see also Chapter 46).

This chapter reviews the current strategies for the diagnosis, reviews the staging system, and describes the current treatment of lung cancer. As much as possible, evidence-based review of the best currently available literature has been included. The role of the pulmonologist is described for every aspect of lung cancer care, from diagnosis to staging to caring for the complications of the disease itself and the complications of cancer treatment.

SCREENING FOR LUNG CANCER

The U.S. Preventive Services Task Force now recommends screening for lung cancer with low dose *computed tomography* (CT) in high-risk patients (see Chapter 18). Before 2013, there was insufficient evidence to support screening for lung cancer.³ For example, the 2004 U.S. Preventive Services Task Force position was based on the results of five randomized, controlled trials that suggested that neither chest radiography nor sputum cytology satisfies the primary criterion of a beneficial screening test: a reduction in lung cancer mortality.⁴⁻⁶ One deficiency was that most of these studies did not include a “no screening” arm. Others arguably had an inadequate sample size. In 2011, the results of the lung arm of the National Cancer Institute’s Prostate, Lung, Colorectal, and Ovarian Trial demonstrated that, in

a randomized trial of chest radiography versus no screening in a low-risk population of both genders, there was no reduction in mortality from lung cancer in the chest radiography screened group compared with usual care.⁷

Chest CT has been shown to be much more sensitive for detecting pulmonary nodules than the standard chest radiograph. There have been a number of single-arm screening trials utilizing *low-dose computed tomography* (LDCT), defined as a single breath-hold scan that exposes the patient to a five to six times smaller radiation dose than a standard CT scan, with or without sputum cytology.^{4,8-13} Although these trials consistently showed that chest CT detects more lung cancers than chest radiography, they were not designed to provide information on mortality benefit. Trials without control arms can be subject to different potential sources of bias.^{10,14} *Lead-time bias* is the detection of tumors earlier in their course; *length-time bias* is the greater detection of less aggressive, slower-growing tumors than more aggressive, faster-growing tumors; and *overdiagnosis* is the detection of tumors that would otherwise never cause symptoms or death.

The *National Lung Cancer Screening Trial* (NLST) is the first large-scale randomized trial to demonstrate a convincing mortality benefit for LDCT lung cancer screening in high-risk individuals. The trial included 33 centers across the United States. Eligible participants were between ages 55 and 74 years at the time of randomization, had a history of at least 30 pack-years of cigarette smoking, and, if former smokers, had quit within the past 15 years.¹⁵ A total of 53,454 persons were enrolled; 26,722 were randomly assigned to screening with LDCT and 26,732 to screening with chest radiography. Any noncalcified nodule found on LDCT measuring at least 4 mm in any diameter and chest radiographic images with any noncalcified nodule or mass were classified as positive. The LDCT-screened group had a substantially higher rate of positive screening tests compared with the radiography group (round 1: 27.3% vs. 9.2%; round 2: 27.9% vs. 6.2%; round 3: 16.8% vs. 5%). Overall, 39.1% of participants in the LDCT group and 16% in the radiography group had at least one positive screening result. Of those with a positive screening result, the false-positive rate was 96.4% in the LDCT group and 94.5% in the radiography group.

In the LDCT group, 649 cancers were diagnosed after a positive screening test, 44 after a negative screening test, and 367 among participants who either missed the screening or received the diagnosis after the completion of the screening phase. In the radiography group, 279 cancers were diagnosed after a positive screening test, 137 after a negative screening test, and 525 among participants who either missed the screening or received the diagnosis after the completion of the screening phase. There were a total of 356 deaths from lung cancer in the LDCT group and 443 in the chest radiography group, with a relative reduction in the rate of death from lung cancer of 20% with LDCT screening. Overall mortality was reduced by 6.7%. The number needed to screen with LDCT to prevent 1 death from lung cancer was 320, which is comparable to the numbers in studies on screening mammography for breast cancer in women older than 50 years.

One of the concerns with using LDCT for lung cancer screening is the high rate of positive test results necessitat-

ing further workup. Investigators from the NELSON study demonstrated that this can be overcome by using semiautomated volumetry software to measure diameter and volume doubling time.¹⁶ Growth was defined as a change in volume between the first and the second scan of 25% or greater. Nodules meeting growth criteria were then classified into three categories based on volume doubling time (<400 days; 400–600 days; >600 days). This approach to nodule management resulted in a decrease in the rate of positive test results at baseline from 30% to 2%. The final results regarding the reduction in mortality from lung cancer in this trial are pending.

Despite the impressive results from NLST in high-risk adults, the ability to generalize the results to other populations has been questioned. Participants in the NLST were enrolled in urban tertiary care hospitals with expertise in all aspects of cancer care. LDCT studies were interpreted by dedicated chest radiologists with expertise in characterizing nodules and providing appropriate recommendations for follow-up. As a result, few patients required further invasive testing, and radiographic follow-up was sufficient for many.

In contrast, community practice gives rise to the potential for considerable variation in the management of solitary pulmonary nodules identified by screening LDCT. One study demonstrated a twofold variation among geographic regions in use of CT-guided biopsy, ranging from 14.7 to 36.2 per 100,000 adults. This substantial variation in the management of solitary pulmonary nodules may lead to an increased number of invasive procedures with risk of harm. For instance, complications from transthoracic biopsies include a 1% rate of bleeding (with one third of affected patients requiring transfusion) and a 15% rate of pneumothorax. More than 6% of CT-guided biopsies result in a pneumothorax requiring chest tube drainage, a clinically important complication that results in pain, serial imaging with radiation exposure, and hospitalization. Older patients and those with *chronic obstructive pulmonary disease* (COPD) have an increased risk of biopsy-related complications that can result in longer length of hospital stay, contributing both to increased cost and higher rates of respiratory failure that can affect long-term health.¹⁷⁻¹⁹

Another difference between the results of the NLST and community practice is that the mortality from lung cancer surgery was 1% in the NLST, whereas the national average is between 3% and 5% for a lobectomy. Whereas NLST participants were allowed to choose where they had their evaluation and management for screen-detected nodules, many were managed at an NLST site with high volume and dedicated thoracic surgery support, both of which have been shown to have better outcomes.^{20,21} Even though 70 years is the average age at lung cancer diagnosis, only 9% of the NLST study population was older than age 70. The patients enrolled in NLST were younger and healthier than persons who would participate in a broad-based lung cancer screening. Participants had to be medically fit to undergo surgery. Those screened in the NLST were also less likely to be current smokers, less ethnically diverse, and more educated than the general U.S. population.²² These differences follow the healthy volunteer effect of screening trials in which there is a self-selection of persons who are better educated and more health-conscious and who have better access to medical care.²³

The evidence of the NLST contributed to a systematic review that serves as the basis for a multisociety recommendation for screening in those people meeting the NLST entry criteria.²⁴ The caveat to the recommendations is that screening should only be done in those centers with multidisciplinary groups capable of providing comprehensive care as was present in the trial. Based largely in part on the results of the NLST, in 2013, the U.S. Preventive Services Task Force published a draft recommendation giving lung cancer screening a grade B recommendation (moderate certainty that annual screening for lung cancer with LDCT is of moderate net benefit in high-risk asymptomatic persons).²⁵ The U.S. Preventive Services Task Force found there to be adequate evidence to screen asymptomatic patients aged 55 to 79 years with significant tobacco use history. Their assessment was that the moderate net benefit of screening depends on two factors: (1) the accuracy of image interpretation would be comparable to that in the NLST and (2) most false-positive could be handled without invasive procedures.²⁵

There may be potential barriers to lung cancer screening, especially in current smokers. In one study, current smokers were less likely to believe that early cancer detection would result in a good chance of survival. Current smokers are also less likely to consider CT screening for lung cancer (71.2%) than are never smokers (87.6%). In addition, only half of the current smokers surveyed would opt for surgical resection of a screening-diagnosed cancer.²⁶ Finally, it is significant that smokers make up 31% of the population below the poverty line compared with 20% of those at or above the poverty line²⁷; as a result, smokers are likely to be a target population more difficult to reach for large-scale screening in the community.

PRESENTATION

Unfortunately, the symptoms of lung cancer can be nonspecific and variable, thereby delaying diagnosis and frequently leading to an advanced stage at the time of diagnosis. The focus of an initial patient evaluation should include signs and symptoms related to the following: local tumor effects, extension of disease into the thoracic cavity, radiologic correlation, paraneoplastic syndromes, and distant metastatic disease. Whereas only 40% of patients with lung cancer in a screened high-risk outpatient population had symptoms, 98% of patients in a hospitalized population presented with symptoms.^{28,29} In general, only approximately one fourth of patients are asymptomatic at the time lung cancer is diagnosed, and these patients are more likely to have less advanced disease.³⁰ Table 53-1 displays some of the common symptoms associated with the presentation of lung cancer. Most are nonspecific; however, some clues can be gained from the history, thus raising the clinician’s suspicion that lung cancer is present.

Although many smokers cough, lung cancer patients usually admit to a change in the character of their cough. The cough can increase in frequency or strength, or may not be relieved with local measures. Chest pain can be present in 25% to 50% of patients at the time of presentation for evaluation for lung cancer.^{28,31} The pain is generally dull in nature, tends to be persistent, remains in the same

Table 53-1 Presenting Symptoms with Bronchogenic Carcinoma

Symptoms and Signs	Frequency, %
Cough	8–75
Weight loss	0–68
Dyspnea	3–60
Chest pain	20–49
Hemoptysis	6–35
Bone pain	6–25
Clubbing	0–20
Fever	0–20
Hoarseness	2–18
Weakness	0–10

Dysphagia	0–2
Wheezing and stridor	0–2

Modified from references 31 and 290 to 295.

location, and is not relieved with local measures. Chest pain is usually related to involvement of the pleura but can be related to extension into the mediastinum or chest wall. However, chest pain in and of itself does not preclude the patient from consideration for surgery with curative intent. Dyspnea is frequently a complaint of patients who present with bronchogenic carcinoma, noted in half of all new patients at presentation.²⁸ A partial list of the reasons for dyspnea related to lung cancer includes pulmonary embolism, superior vena cava (SVC) syndrome, deconditioning, reactive airway disease, endobronchial obstruction with tumor, prior obstructive pneumonia, hemoptysis, hemorrhage, malignant pleural effusion, and extrinsic compression of the airway by tumor.

Hemoptysis in a smoker should raise suspicion of lung cancer. Hemoptysis can present as blood streaking of the sputum and can be noted over a lengthy period of time before presentation to the physician’s office because the patient attributes it to smoking-related bronchitis. The clinician should not be led astray, even if the chest radiograph is normal, because up to 5% of patients with hemoptysis and a smoking history and a normal radiograph can harbor lung cancer.³² Because of the vascular nature of lung cancer, patients can also present with massive hemoptysis.

Weight loss, a nonspecific symptom, in the right clinical setting should raise the suspicion of both lung cancer and metastatic disease. Weight loss alone has been correlated with an advanced presentation and poor outcome in lung cancer cases.

In summary, patients with lung cancer can present asymptotically or with relatively nonspecific symptoms of underlying pulmonary disease. There are often clues in the history that should alert the clinician that lung cancer is a possibility and further investigation is warranted.

LUNG CANCER STAGING

Perhaps the most critical role of the pulmonologist in the management of lung cancer is in the diagnostic and staging

evaluation of the patient. Accurately staging patients with newly diagnosed lung cancer is critical because staging dictates the patient's treatment options and predicts survival. It is intuitive that early-stage disease has a much better survival than late-stage disease. What may not be so obvious is that simple staging procedures are available to the diagnostician that can help stage patients accurately. The treatment options for lung cancer have now evolved so that treatment for patients in different stages is vastly different. In general, stage I (early-stage lung cancer) is treated with surgery alone. Stage II lung cancer (a less common stage, intermediate between early and locally advanced) is treated with surgery followed by adjuvant chemotherapy. Stage IIIA and B (locally advanced lung cancer) is treated with a combination of chemotherapy and radiotherapy, and stage IV (metastatic disease) is treated with chemotherapy alone. However, there are important exceptions to these general rules that are discussed later in this chapter.

The staging of *non-small cell lung cancer* (NSCLC) using the *tumor-node-metastasis* (TNM) classification underwent a major revision in 2007.^{33,34} The new staging system is remarkable in that it is based on more than 100,000 cases of lung cancer from 23 institutions, 12 countries, and 3 continents. The data are robust, internally validated, and externally validated against the Surveillance Epidemiology and End Results cancer registry.³³ Tables 53-2 and 53-3 show the current TNM descriptors and stage groupings.

There are several important changes adopted in the 2007 revision. The main modifications are in the T and M classification; the N status remains the same. Within the T classification, tumor size was found to be an important prognosticator and the T factor was subdivided based upon five different size criteria. Because survivorship was better than previously thought, a primary tumor with satellite nodules in the same lobe was reclassified from T4 to T3 and a tumor with additional nodules in a different lobe of the ipsilateral lung was moved from an M1 designation to T4. This change in classification and stage allows more patients to be considered for surgery. Malignant pleural effusion was reclassified from T4 (or stage IIIB) disease to M1 disease because the survival of patients in this group was found to resemble the survival of those with metastatic disease more closely than those with locally advanced disease. Another significant change is that the M status is now split into M1a (metastatic disease confined to the chest) and M1b (extrathoracic metastatic disease) because survival was found to be better in those patients with metastatic disease confined to the thorax compared with those with extrathoracic metastases.

Whereas the TNM staging system is applied to NSCLC, a more simplified version is employed for patients with *small cell lung cancer* (SCLC). In this classification, patients are classified as having limited or extensive disease. *Limited disease* (LD) is disease limited to one hemithorax, although it can include supraclavicular and mediastinal lymphadenopathy; *extensive disease* (ED) is any disease outside of the hemithorax. The implication in this classification is that LD is treated with chemotherapy and radiotherapy and ED is treated with chemotherapy alone.³⁵ Malignant pleural effusion can technically be categorized as LD in the staging classification for SCLC if the patient otherwise meets criteria. However, for all intents and purposes, patients with

Table 53-2 Tumor-Node-Metastasis (TNM) Descriptors in the Revised 7th Edition of the TNM Classification of Lung Cancer

T (PRIMARY TUMOR)	
TX	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor ≤ 3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)*
T1a	Tumor ≤ 2 cm in greatest dimension
T1b	Tumor > 2 cm but ≤ 3 cm in greatest dimension
T2	Tumor > 3 cm but ≤ 7 cm or tumor with any of the following features (T2 tumors with these features are classified T2a if < 5 cm) Involves main bronchus, ≥ 2 cm distal to the carina Invades visceral pleura Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumor > 3 cm but ≤ 5 cm in greatest dimension
T2b	Tumor > 5 cm but ≤ 7 cm in greatest dimension
T3	Tumor > 7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumor in the main bronchus < 2 cm distal to the carina* but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung or separate tumor nodule(s) in the same lobe
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina; separate tumor nodule(s) in a different ipsilateral lobe
N (REGIONAL LYMPH NODES)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M (DISTANT METASTASIS)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural (or pericardial) effusion†
M1b	Distant metastasis

*The uncommon superficial spreading tumor of any size with its invasive component limited to the bronchial wall, which may extend proximally to the main bronchus, is also classified at T1.

†Most pleural (and pericardial) effusions with lung cancer are due to tumor. In a few patients, however, multiple cytopathologic examinations of pleural (pericardial) fluid are negative for tumor, and the fluid is nonbloody and is not an exudate. Where these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging element and the patient should be classified as T1, T2, T3, or T4.

malignant pleural effusions and SCLC have the same characteristics as those with ED, and the large cooperative group trials have treated them as such.

Some important nuances to staging are described in detail later in this chapter. However, there are certain tenets of staging that must be emphasized. Before classifying a patient within a certain stage, the clinician should make every effort to verify any noninvasive radiologic findings with tissue confirmation of malignancy. This is particularly important when surgical resection would be precluded based on noninvasive radiologic tests. Thus a patient who would otherwise be resectable except for a single abnormality suspicious for metastasis should have tissue confirmation of that abnormality before being deemed unresectable. As is pointed out later in this chapter, no noninvasive radiologic study is infallible. In studies of the mediastinum, false-positive findings range from 12% in *positron emission tomography* (PET) scans to nearly 20% in CT scans (eFigs. 53-1 and 53-2) with lower false-positive findings using integrated PET-CT, at the cost of lower sensitivity.^{36,37} Therefore reliance on the scan alone to predict malignancy is simply not appropriate.

Staging can be accomplished by a number of noninvasive and invasive studies. The choice of the most appropriate study rests with the clinician and is based on how the patient presents. Some patients—for example, those with isolated solitary pulmonary nodules—may be referred for immediate surgical resection as both a diagnostic and a therapeutic maneuver. Others, such as those with extremely poor performance status or those suspected of widely metastatic disease, may undergo no testing at all. The next sections present a discussion of the attributes of each of the staging options available, divided into noninvasive and invasive techniques.

NONINVASIVE STAGING TECHNIQUES

CHEST RADIOGRAPHY

Many lung cancers are detected initially by plain chest radiograph. In certain situations, chest radiography may be sufficient to detect spread to the mediastinum. For example, the presence of bulky lymphadenopathy in the superior or contralateral mediastinal areas may be considered adequate evidence of metastatic disease to preclude further imaging evaluation of the chest. This may be particularly true if the patient is too ill or unwilling to undergo treatment of any kind. Still, most patients should undergo a chest CT scan unless they are so debilitated that no further evaluation or treatment is planned. The chest radiograph is simply too insensitive a measure of mediastinal lymph node involvement with lung cancer and thus further noninvasive or invasive assessment is usually necessary.

CHEST COMPUTED TOMOGRAPHY

The vast majority of patients who present with lung cancer will undergo chest CT, which can confirm the suspicion of lung cancer or raise the suspicion of an alternate diagnosis. CT is helpful in defining the size, location, and characteristics of the primary mass (e.g., circumscribed, spiculated, calcified), the presence or absence of lymphadenopathy, and, if performed through the adrenal glands, the presence of abnormalities in the liver and adrenal glands. The bony structures of the thoracic cavity can also be evaluated by chest CT.

Chest CT is the most widely available and commonly used noninvasive modality for evaluation of the mediastinum in lung cancer. Numerous studies of CT have been performed comparing clinical staging by CT with the “gold standards” of mediastinoscopy or surgery. The results demonstrated that, regardless of the lymph node size used as a threshold for defining malignant adenopathy, CT findings in isolation could not be considered as conclusive evidence that lymph nodes were malignant. In other words, in all studies, there are meaningful numbers of false-positive cases detected by CT (see eFigs. 53-1 and 53-2). The vast majority of reports evaluating the accuracy of CT for mediastinal lymph node staging have employed the administration of intravenous contrast material. Although contrast is not absolutely necessary in performing chest CT for this indication, it is helpful to distinguish vascular structures from lymph nodes as well as to delineate mediastinal invasion from centrally located tumors. The most widely accepted criterion for an abnormal lymph node on CT is a lymph node with a diameter of 1 cm or greater across the short axis.

The *American College of Chest Physicians* (ACCP) compiled the studies assessing the performance characteristics of CT for staging the mediastinum in a meta-analytic format.³⁸ Thirty-five studies were identified, comprising 5111 evaluable patients. The pooled sensitivity of CT for staging the mediastinum was 51% (95% CI, 47% to 54%) and the pooled specificity was 86% (95% CI, 84% to 88%). The corresponding positive and negative likelihood ratios were 3.4 and 0.6, respectively, confirming that CT has a limited

ability to either confirm or exclude mediastinal metastasis.³⁸ However, because CT guides the selection of nodes for biopsy by mediastinoscopy or transbronchial, transthoracic, or transesophageal needle aspiration, it remains an important diagnostic tool in lung cancer. The limitation of CT-based mediastinal lymph node evaluation is evident in that 5% to 15% of patients with clinical T1N0 lesions will be found to have positive lymph node involvement by surgical lymph node sampling (eFig. 53-3).³⁹ Perhaps the most important message in evaluating the accuracy of CT is that approximately 40% of all nodes deemed malignant by CT criteria are actually benign (see eFigs. 53-1 and 53-2), depending on the patient population.⁴⁰ Specificity can be affected by clinical factors such as the presence of obstructive pneumonitis.⁴⁰ There is no node size that can reliably determine stage and operability. When CT criteria for identification of a metastatic node are met, the clinician must still prove beyond reasonable doubt by biopsy or resection that the node is indeed malignant. Given the limitations of the imperfect sensitivity and specificity of CT, it is usually inappropriate to rely solely on CT to determine mediastinal lymph node status. Nonetheless, CT continues to play an important and necessary role in the evaluation of patients with either a known or suspected lung cancer who are eligible for treatment.³⁷

CT can also be helpful in the evaluation of pleural effusion in patients with lung cancer. The CT scan can indicate the presence or absence of fluid, the contour of the pleural space, and whether or not nodules or masses are present on the pleural surface (eFig. 53-4A and B). However, the clinician should interpret these findings with caution because pleural disease can predate cancer and the presence of pleural effusion does not guarantee that the cytology will be positive. This is an important staging issue because the finding of malignant pleural effusion in NSCLC is considered evidence of metastatic disease (stage IV). If the pleural fluid has benign cytology (e.g., it represents fluid from obstructive pneumonia), then the patient may still be considered for surgical resection. To resolve this issue, recommendations have been made to perform thoracentesis with cytology on two separate occasions, followed by thoracoscopy to evaluate the pleural surface directly (eFig. 53-5). If the patient remains cytology-negative, then the patient should be considered to be at the lower, nonmetastatic stage and be treated accordingly. Thoracoscopy can be helpful in differentiating the extent of the primary tumor involvement into or through the pleura but, at times, open thoracotomy is needed to sort out this issue. (See Chapters 24 and 82.)

POSITRON EMISSION TOMOGRAPHY

Perhaps the single most notable addition to the staging armamentarium for the evaluation of lung cancer is PET (see Chapter 21). Because the image is created by the biologic activity of neoplastic cells, PET is a metabolic imaging technique based on the function of a tissue rather than on its anatomy. Lung cancer cells demonstrate increased cellular uptake of glucose and a higher rate of glycolysis when compared with normal cells.⁴¹ The radiolabeled glucose analogue ¹⁸F-fluorodeoxyglucose (FDG) undergoes the same cellular uptake as glucose but, after phosphorylation, is not further metabolized and becomes trapped in cells.⁴²

Accumulation of the isotope can then be identified using a PET detector. Specific criteria for an abnormal PET scan are either a standard uptake value of greater than 2.5 or uptake in the lesion that is greater than the background activity of the mediastinum (see eFig. 53-1B and C, eFig. 53-3B, E, and F, and Fig. 21-1F-J). It has proved useful in differentiating neoplastic from normal tissues. In two well-performed studies that evaluated the use of PET in the preoperative setting for lung cancer,^{43,44} nearly 20% of patients were staged differently after evaluation by PET (see eFigs. 53-1, 53-2, and 53-3, and Fig. 21-3). However, the technique is not infallible because certain nonneoplastic processes, including granulomatous (eFig. 53-6) and other inflammatory diseases and infections may also demonstrate positive PET imaging. Furthermore, size limitations are also an issue, with the lower limit of resolution of the study being approximately 7 to 8 mm depending on the intensity of uptake of the isotope in the abnormal cells (eFig. 53-7A-D).⁴³ One should not rely on a negative PET finding for lesions less than 1 cm on CT.

A burgeoning number of studies in the last several years have reported on the utility of PET in the assessment of the mediastinum in patients with lung cancer. Increasing availability of the technology now allows PET to be used widely as a diagnostic tool. PET is primarily a metabolic examination and has limited anatomic resolution. It is possible for PET to identify lymph node stations but not individual lymph nodes. CT provides much more anatomic detail but lacks the functional information provided by PET. The third edition of the ACCP guidelines on lung cancer reviewed the complexity surrounding PET.³⁷ While PET provides information about the primary tumor, mediastinal lymph nodes, and sites of distant metastasis, the contribution that it makes to the stage evaluation is influenced by a multitude of factors. These include the probability of cancer, likelihood of metastasis, and the extent that the investigation for metastases has been completed by other modalities.

To date, there have been five randomized controlled trials to evaluate the role of PET.⁴⁵⁻⁴⁹ The variation in results among the studies was likely due to the significant differences among the patients involved, the prior evaluations, and risk for advanced disease. While two of the studies demonstrated a reduction in the number of noncurative resections from 40% to 20%,^{46,49} another detected no difference in the number of thoracotomies performed or of sites of distant metastasis.⁴⁵ This latter study primarily involved stage I patients with extensive preenrollment imaging explaining why there was no difference detected between the PET and conventional staging arms.

Population-based studies using the U.S. National Cancer Data Base and the Surveillance, Epidemiology and End Results registry suggest that the use of PET has had a positive impact on stage migration from stage III to stage IV classification (eFig. 53-8).^{50,51} Conversely, PET adds little to the staging of patients with clinical stage I cancers.^{50,52} PET is also of limited value in those with ground-glass opacities with or without a solid component because these patients are at low risk for nodal and distant metastatic disease.⁵³

Compared with conventional staging, staging by PET is, on average, 20% more correct in identifying nodal or distant metastasis in randomized controlled trials.⁴⁴⁻⁴⁶ Confirmation of PET findings, however, is imperative because, as is

known for CT, PET can be wrong. PET also carries the possibility of incorrectly upstaging a patient. Whereas a negative mediastinal PET may obviate the need for mediastinoscopy before thoracotomy in certain situations, a positive mediastinal PET should not negate further evaluation or the possibility of resection. In the latter case, lymph node sampling should still be pursued because the possibility of a false-positive PET scan cannot be ignored.

Where PET is available, a PET scan should be obtained during the staging evaluation for lung cancer.⁵⁴ Newer technology includes CT-PET fusion, a single machine that incorporates CT and PET during the same scan. This allows the clinician to obtain anatomic (CT) and functional (PET) images simultaneously. Studies suggest an improvement in the number of patients correctly staged with this modality over CT or PET alone.^{55,56} The future of PET in lung cancer may also include its use to evaluate response to treatment. Due to potential false positive images, the optimal timing for PET following treatments will require further evaluation, especially when chest radiotherapy is used. For example, it may be more useful later in the post-*stereotactic body radiation therapy* (SBRT) period (i.e., after the first year) rather than early in the period (i.e., within the first 3 to 6 months).^{56a}

MAGNETIC RESONANCE IMAGING

There are very few circumstances in which *magnetic resonance imaging* (MRI) is a useful tool in staging lung cancer. However, MRI can be useful in evaluating superior sulcus tumors, especially for possible invasion of the brachial plexus, and for evaluating vertebral invasion.

SEARCH FOR METASTATIC DISEASE

The purpose of extrathoracic scanning in NSCLC is usually to detect metastatic disease at common metastatic sites, such as the adrenal glands, liver, brain, and skeletal system, thereby sparing the patient fruitless surgical intervention.⁵⁷ CT of the chest (eFig. 53-9A), CT (eFig. 53-9C) or MRI with contrast of the brain, and ^{99m}Tc nuclear imaging of the skeletal system are the conventional staging studies when the clinician needs to evaluate for metastatic disease. The use of whole-body PET and PET-CT (see eFig. 53-8) for extrathoracic staging has advanced the field of metastatic disease evaluation. Studies demonstrate that PET and PET-CT outperform conventional staging tests in the evaluation of metastatic disease to key specific distant sites including adrenal glands, liver, and bone (see eFig. 53-8). PET reveals unsuspected metastases in 6% to 37%⁵⁸⁻⁶¹ (see eFig. 53-8 and Fig. 21-4). This allows for more accurate TNM staging,⁶² stage shift,^{50,63} and changes in management including more appropriate consideration of surgical candidacy.^{62,64,65} Detection of brain metastases is a problem for PET because the high background brain FDG uptake can mask the small size of most brain metastases, which can be either hypermetabolic or hypometabolic.⁶⁶ There is some evidence to suggest that integrated PET-CT has an accuracy that nears diagnostic brain CT (see eFig. 53-8B).⁶⁷

The initial clinical evaluation may reveal abnormalities, such as abnormal symptoms, physical findings, and routine blood tests, that then lead to an expanded clinical evaluation

Table 53-4 Expanded Clinical Evaluation

SYMPTOMS ELICITED IN HISTORY
Constitutional—weight loss >10 lb (>4.5 kg)
Musculoskeletal—focal skeletal pain
Neurologic—headaches, syncope, seizures, extremity weakness, recent change in mental status
SIGNS FOUND ON PHYSICAL EXAMINATION
Lymphadenopathy (>1 cm)
Hoarseness, superior vena cava syndrome
Bone tenderness
Hepatomegaly (>13-cm span)
Focal neurologic signs, papilledema
Soft tissue mass
ROUTINE LABORATORY TESTS
Hematocrit < 40% in males
Hematocrit < 35% in females
Elevated alkaline phosphatase, GGT, AST, calcium

AST, aspartate aminotransferase; GGT, gamma-glutamyl transpeptidase.

(Table 53-4).⁵⁷ If a patient has abnormalities on these clinical evaluations, scans will be abnormal in around 50% of cases. The third iteration of the ACCP guidelines for NSCLC staging recommends PET to evaluate for metastasis (except for metastasis to the brain) for patients with a normal clinical evaluation and no suspicious extrathoracic abnormalities on chest CT being considered for curative-intent treatment.³⁷ Advanced thoracic lesions and mediastinal lymphadenopathy are important variables because these are associated with more scan abnormalities.^{57,68} This is particularly true for N2 disease, in which asymptomatic metastases have been documented at a higher rate than would have been expected (see eFig. 53-8).⁶⁸ Although several studies have documented a higher incidence of brain metastases in patients with adenocarcinomas than in those with squamous cell cancers,^{69,70} the largest single series of patients with stage I and II lung cancer found no difference.⁷¹

Several important caveats must be considered in the search for metastatic disease. First and foremost, there is the problem of false-positive scans. Adrenal adenomas (present in 2% to 9% of the general population), hepatic cysts, degenerative joint disease, old fractures, and a variety of nonmetastatic space-occupying brain lesions are present in the general population. When clinically indicated, additional imaging studies, biopsies, or both are performed to establish the diagnosis; however, complications and costs resulting from such subsequent investigations have received less attention.⁷² There is also the problem of false-negative scans, scans that fail to detect actual metastases. For example, in a CT study of the adrenal glands, Pagani⁷³ found metastatic NSCLC by percutaneous biopsy in 12% of radiologically normal adrenal glands. An additional problem is that the studies in this area often fail to specify exactly which elements make up the prescan clinical evaluation or that the studies use differing clinical indicators. For example, organ-specific findings such as headache and non-organ-specific complaints such as weight loss are both important.^{74,75} In addition, in many studies, abnormal findings on scans have not been pursued with biopsies to prove metastatic disease. Finally, there are few prospective randomized trials and outcome studies to guide appropriate use

and interpretation of extrathoracic scanning. It is hoped that careful studies will improve the workup of patients with lung cancer.

Adrenal and Hepatic Imaging

It is relatively common to encounter adrenal masses on routine CT, but many of these lesions are probably unrelated to the malignant process. A unilateral adrenal mass in a patient with NSCLC is more likely to be a metastasis than a benign lesion according to some studies,^{76,77} but not others.^{78,79} In the setting of clinical T1N0 NSCLC, adenomas predominate,^{80,81} whereas in the setting of large intrathoracic tumors or other extrathoracic metastases, adrenal metastases are more common.^{77,82} Many studies suggest that the size of a unilateral adrenal abnormality on CT is an important predictor of metastatic spread, but this is not a universal finding.⁸³ Lesions larger than 3 cm are more likely to signify metastases (see eFig. 53-9A), but benign disease is still possible.

For adrenal masses, CT, MRI, PET, percutaneous biopsy, and even adrenalectomy can be used to help distinguish benign from malignant disease. Well-defined, low-attenuation (fatty) lesions with a smooth rim on unenhanced CT are more likely to be benign adenomas,⁸⁴⁻⁸⁶ but the CT appearance of many lesions is insufficiently distinctive.⁸⁴ Follow-up scanning with repeat CT, serial ultrasonography, MRI (especially with chemical shift and dynamic gadolinium-enhanced techniques⁸⁷), or 6-β-iodo-¹³¹I-methyl-norcholesterol scanning⁸⁸ can sometimes help with the critical distinction between metastatic disease and adenoma. One study demonstrated the utility of PET-CT in differentiating between benign and metastatic malignant adrenal masses in patients with lung cancer.⁸⁹ In 110 adrenal masses ranging in size from 0.5 to 6.3 cm, the sensitivity, specificity, and accuracy for detecting metastatic disease were 97% (74 of 76), 94% (31 of 34), and 95% (105 of 110), respectively (eFig. 53-10). The positive predictive value was 95% (74 of 77), and the negative predictive value was 94% (31 of 33).

Percutaneous adrenal biopsy is a relatively safe and effective means of achieving a definitive diagnosis in doubtful cases and is especially important when the histology of the adrenal mass will dictate subsequent management.^{90,91} However, this procedure may be nondiagnostic or infeasible due to anatomic constraints. When insufficient material results from a biopsy, repeat aspiration or even adrenalectomy should be considered.^{83,84}

Most liver lesions are benign cysts and hemangiomas, but CT with intravenous contrast (or ultrasound) is often required to establish a likely diagnosis.³⁹ Percutaneous biopsy can be performed when diagnostic certainty is required. PET can detect liver metastases with a diagnostic accuracy ranging from 92% to 100% (eFig. 53-11) with rare false-positive results; however, the data in NSCLC are currently limited.⁹²⁻⁹⁴

Brain Imaging

In most studies, the yield of CT/MRI of the brain in NSCLC patients with negative clinical examinations is 0% to 10%,^{57,95-100} possibly rendering the test cost-ineffective.¹⁰¹ The negative predictive value of the clinical evaluation in this setting is 95% (range, 91% to 96%).

An association of positive findings between brain metastases and N2 disease in the chest and adenocarcinoma has been described.^{70,97,99} The false-negative rate, wherein patients return with brain metastases within 12 months of the original scan, is reported to be 3%.⁹⁹ False-positive scans can be a problem in up to 11% of cases due to brain abscesses, gliomas, and other lesions¹⁰²; therefore biopsy may be essential in cases in which management is critically dependent on the histology of the brain lesion.

MRI is more sensitive than CT of the brain and picks up more lesions and smaller lesions¹⁰³ but, in some studies, this has not translated into a clinically meaningful difference in terms of survival.¹⁰⁴ Although studies show that MRI can identify additional brain lesions in a particular patient, there are no studies that show that MRI is better than CT in its ability to identify additional patients with brain metastases from lung cancer. Therefore CT is an acceptable modality for evaluating patients for metastatic disease.³⁷ However, MRI remains the preferred modality at many centers.

Bone Imaging

False-positive abnormalities in radionuclide bone scintigraphy are common concerns because of the frequency of degenerative and traumatic skeletal damage and the difficulty in obtaining a definitive diagnosis via follow-up imaging or biopsy. With a negative clinical assessment, the negative predictive value for radionuclide bone imaging is 90%. PET has excellent performance characteristics for determining bone metastases (eFig. 53-12) with a specificity, sensitivity, negative predictive value, and positive predictive value all greater than 90%.^{94,105} The accuracy of PET was superior to radionuclide bone scanning in direct comparison studies.¹⁰⁶⁻¹⁰⁸

SUMMARY

The noninvasive clinical staging of lung cancer relies on the clinical evaluation and a number of readily available staging studies. The clinician must be wary of abnormal scans that may falsely suggest metastatic disease to the mediastinum and distant sites. Tissue confirmation by whatever means necessary is the rule rather than the exception before deciding on correct stage and the most appropriate treatment. If the patient has clinical findings indicative of metastatic disease, further evaluation is necessary because nearly 50% of the time the patient will have metastases. Even if the clinical evaluation is normal and imaging does not demonstrate suspicious extrathoracic abnormalities, PET imaging should be done where available in those being considered for curative-intent treatment.³⁷

INVASIVE DIAGNOSTIC AND STAGING TECHNIQUES

There are a myriad of methods that can be used to diagnose and stage patients with lung cancer. In certain circumstances, this is accomplished with a single test. For example, a positive percutaneous biopsy (or endoscopic ultrasound-guided fine-needle aspiration) of the adrenal

gland performed as a first test in a patient with a lung mass will provide both a diagnosis and a stage (stage IV) simultaneously. Every effort should be made to use the least invasive, most accurate procedure to expedite the patient's treatment, to minimize patient discomfort and inconvenience, and to ensure that the most appropriate treatment is rendered.

SPUTUM CYTOLOGY

Sputum cytology is the least invasive method for obtaining a diagnosis of lung cancer. Its accuracy depends on the expertise of the health care team in obtaining the sample (three samples are required), the preservation technique, and the size and location of the lesion. Central lesions are more likely to yield positive cytologic results than are peripheral lesions.¹⁰⁹ Sputum cytology should be obtained in all patients with central lesions who are at risk for more invasive biopsy techniques and considered in those with hemoptysis with or without a mass on chest radiography. Previously published systematic reviews have summarized the performance characteristics for sputum cytology for the diagnosis of suspected lung cancer.^{109,110} The ranges for sensitivity and specificity were 42% to 97% and 68% to 100%, respectively. The accuracy of sputum cytology is highly variable, so, in patients suspected of having lung cancer with negative sputum cytology, further testing should be performed.⁵³

TRANSTHORACIC NEEDLE ASPIRATION

Transthoracic needle aspiration (TTNA), usually under ultrasound (see Fig. 19-3), CT, or fluoroscopic guidance, is an expedient and relatively safe way to diagnose the primary tumor mass and establish a diagnosis of lung cancer (see Figs. 19-1 and 19-6). As a general rule, if a lesion is less than 3 cm in size and lateral to the mid-clavicular line (eFig. 53-13), TTNA should be considered if tissue diagnosis is necessary. One important point about TTNA or other nonsurgical biopsy techniques for peripheral pulmonary lesions is that they afford no preoperative benefit because they do not eliminate the need for surgery in most cases.¹¹¹ For a patient presenting with a solitary pulmonary nodule suspicious for malignancy (e.g., noncalcified, upper lobe, spiculated lesion in a long-term smoker), the diagnosis, stage, and therapy can be accomplished simultaneously with a thoracotomy and surgical resection. Thus TTNA may be essential only in certain situations: patients who are poor surgical candidates but who require tissue diagnosis prior to treatment, patients in whom a noncancerous lesion is strongly suspected (see Fig. 19-7), patients who request that a diagnosis of cancer be confirmed before considering surgery, and patients with high likelihood of metastatic disease (see Fig. 19-2). The sensitivity and specificity of TTNA are 90% and 97%, respectively¹⁰⁹ (see Chapter 19).

One drawback of TTNA is the risk of pneumothorax. Several investigations have reported a 15% to 45% risk of pneumothorax for CT-guided TTNA.^{17,112-114} Although pneumothorax may lead to hemodynamic compromise without therapeutic tube thoracostomy, in most cases of pneumothorax secondary to TTNA, treatment is not

required.¹¹⁵ The primary factors shown to increase the risk or incidence of pneumothorax are the presence of emphysema, a smaller lesion size, and a greater depth of needle penetration from the pleural surface to the edge of the lesion.

FIBEROPTIC BRONCHOSCOPY

More than 50% of patients with advanced-stage lung cancer will have involvement of the central airways either by bulky endobronchial disease, extension into the airways, or extrinsic compression of the airways by the tumor or by lymphadenopathy.¹¹⁶ Patients with known or suspected lung cancer may have symptoms due to endobronchial involvement that require airway inspection with bronchoscopy: shortness of breath, unilateral wheezing, hemoptysis, and cough. Endobronchial lesions can be visualized easily and biopsied through a flexible bronchoscope. The yield with three or more biopsies should approach 100% for centrally located lesions.^{117,118} Data from 4507 patients revealed that central endobronchial biopsies provide the highest sensitivity (74%), followed by brushings (61%) and washings (47%).¹⁰⁹ The combination provides a diagnosis in 88% of cases.¹⁰⁹ Endobronchial needle aspiration may be helpful especially when a rim of necrotic debris surrounds an endobronchial malignancy, because deeper tissue penetration may access viable tumor cells. The addition of endobronchial needle aspiration to forceps biopsies and brushings may improve sensitivity to 95% for the diagnosis of endobronchial cancer.^{119,120}

Submucosal and Peribronchial Lesions

When lung cancer presents with submucosal infiltration or extrinsic compression from peribronchial disease, endobronchial forceps biopsy has a lower yield (55%) than *transbronchial needle aspiration* (TBNA) (71%).¹²¹ In these situations, normal mucosal markings are often obscured and the surface is replaced with bronchial collateral vessels and firmer surface tissue, which may have to be penetrated to reach malignant cells. In addition, peribronchial tumor may be inaccessible to biopsy forceps. TBNA can be more effective if the lesion is close enough to the tracheobronchial tree to be encountered with a 1.3- to 1.5-cm-long needle. Of note, in cases like this when sampling error may be high, diagnostic yields may be improved by combining different methods or by using with *endobronchial ultrasound* (EBUS)-TBNA, which offers the advantages of real-time ultrasound and an adjustable needle length up to 4 cm.

Navigational Bronchoscopy

Navigational bronchoscopy provides a novel option for the diagnosis of peripheral lung lesions (see Chapter 22). It has a lower pneumothorax risk than TTNA and a higher diagnostic yield for peripheral lesions than traditional bronchoscopy.¹²² In general, there are three types of navigational bronchoscopy: (1) radial probe endobronchial ultrasonography, which is conventional radial EBUS using guide sheaths that allow the use of biopsy tools after successful navigation to the target; (2) virtual bronchoscopy, which creates a CT-based "road map" overlaid on endoscopic real-time images; and (3) electromagnetic navigational bronchoscopy which uses a virtual navigation system with

steerable devices.¹²³ A combination of navigational techniques has been shown to augment the diagnostic yield (88%) when compared to either radial probe endobronchial ultrasonography or electromagnetic navigational bronchoscopy alone.¹²⁴ A meta-analysis reported the accuracy and side effect profile of all available guided bronchoscopy procedures. In 39 studies, which together included more than 3000 patients, the pooled diagnostic yield was approximately 70% (with wide variation) and the pneumothorax rate was less than 2% (need for chest tube insertion less than 1%).¹²⁵ In addition, navigation may be used for placement of fiducial markers for stereotactic radiation treatments.¹²⁶

Bronchoscopy for Staging Lung Cancer

Initially, the role of bronchoscopy in staging lung cancer was limited to the determination of T (tumor) status. Now bronchoscopy has a crucial role in determining the presence of metastatic deposits of tumor in mediastinal lymph nodes, thus contributing to an accurate and a minimally invasive staging method for lung cancer.

The use of traditional TBNA in staging lung cancer has been reported to be both sensitive and specific in diagnosing spread of cancer to lymph nodes.¹²⁷⁻¹²⁹ The overall sensitivity of TBNA for NSCLC is 78% and the specificity is 99%.¹³⁰ The standard method of performing TBNA starts with a CT scan of the chest to guide needle aspirations toward the most involved group of lymph nodes. Lesions localized by CT can be accessed with bronchoscopy by measuring the number of CT slices above or below the carina (or other airway landmarks) and placing the needle the required distance above or below the landmark corresponding to that number of CT slices. When performing TBNA, the question invariably arises about the number of negative passes to perform before stopping. For various reasons, such as patient comfort and safety, need for sedation, and time spent by medical staff, it is imperative to manage the time for bronchoscopy. It has been shown that a plateau in yield for malignancy is achieved after seven passes with the needle through a lymph node.¹³¹ The importance of having a qualified and experienced cytopathologist on site cannot be overemphasized. Thorough interpretation by such individuals who are available for rapid on-site evaluation has been shown to enhance yield from TBNA.¹³² With the assistance of these individuals, the adequacy of sampling can be rigorously assessed. All samples should contain a preponderance of lymphocytes to define true nodal sampling. Specimens without lymphocytes should be deemed unsatisfactory, and the presence of respiratory epithelium should raise concerns about contamination.

TBNA allows for minimally invasive sampling of the mediastinum and hilar lymph nodes and potentially avoids more invasive procedures such as mediastinoscopy, mediastinotomy, and open thoracotomy. There is no doubt that the combined use of TBNA and CT can improve not only the diagnostic but also the staging evaluation of lung cancer. However, thus far, there has been wide variability in training and in usage of this helpful procedure. It is also operator-dependent, with certain techniques allowing for higher yields. See Chapter 22 for an in-depth discussion of bronchoscopy.

ENDOSCOPIC ULTRASOUND

Endoscopic ultrasound (EUS) is another modality that has significantly impacted lung cancer staging, primarily due to its superior ability to sample the posterior mediastinum through the esophageal wall. Currently, EUS with fine-needle aspiration is performed using real-time ultrasound. In pooled analysis of 2433 patients with lung cancer and mediastinal adenopathy, EUS had a sensitivity and specificity of 89% and 100%, respectively.^{37,130,133-156} In patients with lung cancer who have no adenopathy seen on CT, EUS has been shown to sample nodes as small as 3 mm in diameter. This is useful given the high incidence of metastasis found in normal-sized lymph nodes in lung cancer.¹⁵⁷ Based on surgical studies, it may be possible to predict the location of mediastinal lymph node metastases at certain levels based on the location of the tumor. This relationship may influence the use of EUS in certain patients without adenopathy on chest CT. Lymphatic pathways favor spread to aortopulmonary window nodes from left upper lobe tumors and to subcarinal nodes from left and right lower lobe lesions.¹⁵⁸ EUS has been studied in patients with known lung cancer without enlarged mediastinal lymph nodes on CT, and it has detected mediastinal involvement (stage III or IV disease) in up to 42% of cases.¹⁵⁹

In addition, EUS has the advantage of being able to stage lung cancer from locations outside the mediastinum. The left lobe of the liver, a substantial part of the right lobe of the liver, and the left (but not the right) adrenal gland can be identified and sampled in 97% of patients.¹⁶⁰ In addition, left pleural effusions can be visualized and sampled during an EUS procedure. EUS is increasingly being combined with EBUS for minimally invasive staging of lung cancer.¹⁶¹

ENDOBONCHIAL ULTRASOUND

Perhaps the greatest addition in the armamentarium for staging lung cancer is *endobronchial ultrasound with transbronchial needle aspiration (EBUS-TBNA)*. EBUS-TBNA is indicated for the assessment of mediastinal and hilar lymph nodes and diagnosis of lung and mediastinal tumors. It can be used to sample the highest mediastinal (station 1), the upper paratracheal (station 2R, 2L), the lower paratracheal (station 4R, 4L), the subcarinal (station 7), as well as the hilar (station 10) and the interlobar (station 11) lymph nodes (Fig. 53-1A). The para-aortic (station 6), aortopulmonary window or subaortic (station 5), paraesophageal (station 8), and pulmonary ligament (station 9) lymph node stations are usually not accessible by this technique (see Fig. 53-1B). Pooled analysis of 2756 patients shows that EBUS-TBNA has a sensitivity and specificity of 89% and 100%, respectively.³⁷ If a patient presents with a lung mass and mediastinal lymphadenopathy in accessible lymph node stations, EBUS-TBNA should be considered as the test of first choice because this modality can provide a diagnosis and stage simultaneously. In addition, the role of EBUS in lung cancer has expanded to include preoperative mediastinal staging and tissue acquisition for molecular analysis in addition to immunohistochemical staining.¹⁶²⁻¹⁶⁴

The combination of EUS and EBUS has shown better yield than either technique alone. A pooled analysis from 7 studies and 811 patients showed a sensitivity and specificity

of 91% and 100%, respectively.^{37,135,139,140,165-168} These complementary procedures provide near-complete access to the mediastinum for staging,¹³⁵ even in the radiologically normal mediastinum.¹⁴⁰ Among patients with (suspected) NSCLC, a staging strategy combining endosonography and mediastinoscopy compared with mediastinoscopy alone was shown to have greater sensitivity for mediastinal nodal metastases and led to fewer unnecessary thoracotomies.¹⁶⁵

For further discussion of EBUS, see Chapter 22.

MEDIASTINOSCOPY

Mediastinoscopy is the historical gold standard for invasively staging the mediastinum in patients with known or suspected lung cancer; however, if local expertise is available, ultrasound-guided needle techniques (EBUS-TBNA, EUS, or their combination) are now recommended as the best first tests. If there is mediastinal lymph node enlargement regardless of FDG uptake on PET or if there is FDG uptake in a lymph mediastinal node regardless of its size, a surgical mediastinal procedure should be performed before

thoracotomy despite a negative needle technique. Mediastinoscopy is most often used to sample nodes of the paratracheal (station 4), and anterior subcarinal (station 7) region (see Fig. 53-1A). Because the subcarinal area is more difficult to sample, mediastinoscopy has a lower yield for lymph nodes in this area. An extended cervical mediastinoscopy can be carried out to reach aortopulmonary and para-aortic lymph nodes (stations 5 and 6) by using the same cervical incision as mediastinoscopy but dissecting into a different fascial plane. Alternatively, an anterior mediastinotomy (the so-called Chamberlain procedure) may be needed to sample lymph nodes in these aortopulmonary and para-aortic locations (stations 5 and 6) (see Fig. 53-1B). Overall, mediastinoscopy has a reported sensitivity of 78%, with a specificity of 100%.¹³⁰ Mediastinoscopy may also differentiate between stage IIIA and IIIB mediastinal involvement, which may be important for prognosis and potential therapy. As with any surgical procedure, mediastinoscopy has risks and limitations. It requires general anesthesia, with a morbidity of 2% and a mortality of 0.08%.¹³⁰

Figure 53-1 Mediastinal lymph node maps. A and B, the 14 stations for lymph nodes used in lung cancer staging are shown in association with anatomic landmarks. The N2 nodes are within the mediastinal pleural envelope (1-9) and the N1 nodes are outside the mediastinal pleural envelope, in the hilar (10) or intrapulmonary (11-14) locations. a, artery; Ao, aorta; A-P, aortic-pulmonary; PA, pulmonary artery; v, vein. (Redrawn from Mountain CF, Dresler CM: Regional lymph node classification for lung cancer staging. *Chest* 111:1719, 1997.)

Figure 53-1, cont'd.

- Superior mediastinal nodes
- 1 Highest mediastinal
 - 2 Upper paratracheal
 - 3 Pre-vascular and retrotracheal
 - 4 Lower paratracheal (including azygos nodes)

- Aortic nodes
- 5 Subaortic (A-P window)
 - 6 Para-aortic (ascending aorta or phrenic)

- Inferior mediastinal nodes
- 7 Subcarinal
 - 8 Paraesophageal (below carina)
 - 9 Pulmonary ligament
- N2 nodes (1-9) ipsilateral
- N3 nodes (1-9) contralateral or supraclavicular or scalene nodes

- N1 nodes (10-14) ipsilateral
- 10 Hilar
 - 11 Interlobar
 - 12 Lobar
 - 13 Segmental
 - 14 Subsegmental

TREATMENT OF LUNG CANCER

The overall 5-year survival for patients diagnosed with lung cancer is a dismal 14%.¹⁶⁹ This figure has not changed substantially since the 1980s. The survival curves vary by stage, with earlier stage lung cancer patients enjoying a much better survival than patients with later stage disease. Treatment is based on the stage of the disease and the patients' performance status at the time therapy is initiated. In general, early stage disease is surgically managed, locally advanced disease is managed with chemotherapy and radiotherapy, and advanced disease is managed with chemotherapy with supportive care or supportive care alone. This paradigm has shifted toward more multimodality therapy (surgery, chemotherapy, and radiotherapy).¹⁷⁰⁻¹⁷³ This raises the issue of how best to manage patients with newly diagnosed lung cancer through their diagnosis, staging, and therapy. The ACCP guidelines on lung cancer recommend the use of a multidisciplinary lung cancer setting wherein patients can be evaluated by the major disciplines involved in the care of these patients, namely the pulmonologist, the thoracic surgeon, and the medical and radiation oncologists.¹⁷⁴ A "tumor board" that includes the aforementioned specialties, with the addition of chest radiology, pathology, nursing, and social work, should review

all new cases to ensure that patients receive optimal treatment and are considered for enrollment in clinical trials.

In addition to surgery, treatment such as chemotherapy and or radiotherapy can be applied in a neoadjuvant or adjuvant fashion. *Neoadjuvant* therapy indicates therapy given before the main treatment; it has the potential to reduce tumor volume, treat micrometastases, and improve outcomes. *Adjuvant* therapy is therapy given after the main treatment; it is aimed at treating any residual tumor or micrometastases with the aim of preventing tumor recurrence. The efficacy of treatments can be assessed by *median survival time* (MST) or by *progression-free survival* (PFS), the length of time a patient lives with lung cancer before it progresses.

PROGNOSTIC FACTORS FOR LUNG CANCER

Based on an analysis of large databases of inoperable lung cancer cases, the strongest predictors of survival are good performance score (Karnofsky scale), lower extent of disease (stage), age, and absence of weight loss.¹⁷⁵⁻¹⁷⁷ Some reports have shown female gender to be a predictor of better survival, but this varies between studies. Performance score and the presence or absence of symptoms are predictors of outcome even with resectable early-stage disease.¹⁷⁸⁻¹⁸⁰ For

Table 53-5 Summary of Current Treatment Strategies for Non–Small Cell Lung Cancer

Stage	Surgery	Chemotherapy	Radiotherapy	Chemoradiotherapy	Comments
I and II	1st line	Adjuvant—stage IIA, IIB	2nd line	No	Survival improvement with adjuvant therapy (= 5%) Radiotherapy for inoperable patients
IIB (T3N0M0) Pancoast	1st line	No	No	1st line—neoadjuvant	Neoadjuvant chemoradiotherapy improves survival in this subset of stage IIB
IIIA	1st line	Adjuvant treatment—in totally resected IIIA	Controversial	1st line	Combined chemoradiotherapy followed by surgery is feasible, but more data are needed to recommend routinely
IIIB Unresectable	No	No	No	1st line	Treatment similar to unresectable stage IIIA
IV	No	1st line*	No	No	Radiotherapy is used for palliation only All stage IV should have mutational analysis, including <i>EGFR</i> , <i>EML4-ALK</i> , and <i>KRAS</i> .

Bevacizumab is approved as an adjunct to chemotherapy in the first-line setting in patients with nonsquamous histology and no other contraindications.

*The targeted therapies are indicated as first-line treatment for those with advanced NSCLC and documented *EGFR* mutations or *EML4-ALK* fusion. Erlotinib is FDA-approved as first-line treatment of metastatic NSCLC for patients whose tumors have *EGFR* exon 19 deletions or exon 21 (L858R) substitution mutations.

EGFR, epidermal growth factor receptor; FDA, U.S. Food and Drug Administration; NSCLC, non–small cell lung cancer.

example, in stage I NSCLC patients undergoing curative resection, those who were symptomatic at presentation had worse survival than those who were asymptomatic.¹⁷⁹ Although individual reports have noted superior survival for patients with one cell type of NSCLC versus another, the general consensus in the literature is that histologic subtypes of NSCLC are not a major predictor of survival.^{178,179,181} Absence of smoking or smoking cessation has been associated with improved survival. The maximal standard uptake value of the primary tumor on PET has been inversely correlated with survival.¹⁸²

In more recent years, there have been numerous reports that various molecular markers are associated with outcome. Some of the best known markers include *KRAS*, *epithelial growth factor receptor (EGFR)*, *EML4-ALK* translocation, p53, p16, and BCL2. However, in many instances, the results are conflicting about the prognostic significance of these individual molecular markers,¹⁸³⁻¹⁸⁵ perhaps due to the types of cases under review and to individual laboratory variations in techniques for measuring these molecular markers. In a meta-analysis, *KRAS* mutations were associated with poorer survival, especially in adenocarcinoma in which the hazard ratio was 1.6 (95% CI, 1.3 to 2).¹⁸⁶ Testing the genetic profile of samples obtained from metastatic lymph nodes or malignant pleural effusions in those patients with stage III and IV disease has become standard practice, because this allows for the selection of targeted drug therapies specific for the mutation as first-line chemotherapy.

NON–SMALL CELL LUNG CANCER TREATMENT BY STAGE

This section presents a discussion of the treatment of NSCLC by stage and cell type, followed by a discussion of the treatment of SCLC. Table 53-5 presents an overview of treatment strategies for NSCLC based on stage.

Stage I

In the most recent staging system for NSCLC, stage I NSCLC is broken down into stage IA (tumors ≤ 2 cm [T1a] (eFig. 53-14A) and tumors between 2 and 3 cm [T1b]) (see eFig.

53-14B) and stage IB (tumors between 3 and 5 cm [T2a]) (see eFig. 53-15). All stage I tumors are completely surrounded by lung parenchyma greater than 2 cm away from the carina and do not invade the chest wall or parietal pleura (Fig. 53-2). Stage I lung cancer does not include patients who have malignant lymph node disease or patients with metastatic disease. Thus the TNM classification is either T1aN0M0, T1bN0M0 (stage IA), or T2aN0M0 (stage IB). The differences between the two are the size of the primary tumor and the survival after surgical resection. Although stage I disease offers the best chance for long-term survival, the sad fact is that only 15% of all lung cancers present with stage I disease.^{187,188}

The current treatment for stage I lung cancer is surgery alone. The surgical procedure of choice is a lobectomy or pneumonectomy with mediastinal lymph node sampling. It should be recognized that the patient must be a reasonable surgical candidate. The 5-year survival for surgically resected stage IA lung cancer is 73%, whereas the survival for stage IB lung cancer is 58%.³³ Local postoperative radiation for stage I and II lung cancer, after either complete or incomplete resection of the tumor, has not been found to be of any benefit.¹⁸⁷ Postoperative adjuvant chemotherapy has not been shown to improve survival for those with resected stage I disease.¹⁸⁹ A further discussion of postoperative adjuvant therapy is presented later (see “Stage IIIA”).

Some patients are surgically resectable but medically inoperable, usually because the patient does not have the pulmonary reserve to tolerate a lobectomy. These patients, particularly those with T1 tumors, may be able to tolerate a wedge resection or segmentectomy of their tumor as opposed to a lobectomy or pneumonectomy. In such cases, the local recurrence rate is higher than that of a complete resection, but the overall 5-year mortality is no different.¹⁹⁰ However, for patients with smaller peripheral stage I lung cancers, anatomic segmentectomy may offer local control, the opportunity for prolonged disease free survival, and overall survival that is comparable to lobectomy.^{190a} Still, whenever possible, a complete anatomic resection is preferred over a minimal resection. For discussion of

Figure 53-2 Stage I disease. CT (A) and PET (B) scans of a patient with T1N0M0 tumor (arrows).

radiofrequency ablation and other nonsurgical treatments, see Chapter 19.

Patients who are “close calls” for surgery should be thoroughly evaluated by both a pulmonologist and a thoracic surgeon before making a decision on operability. As previously stated, there is a difference between a patient who is resectable and a patient who is operable. Chapter 27 is devoted to the preoperative evaluation of patients with lung disease, but a brief review is warranted here. Patients with a postoperative percent predicted forced expiratory volume in 1 second or diffusion capacity less than 40% will have a higher morbidity and mortality following lung cancer surgery. Patients with borderline values preoperatively should be referred for a differential ventilation-perfusion scan for a better prediction of postoperative function. When there is still a question, a cardiopulmonary exercise test can be obtained. Compared with those with an oxygen consumption greater than 20 mL/kg/min, patients with an oxygen consumption between 11 and 19 mL/kg/min have a higher morbidity but no greater mortality and those with

an oxygen consumption less than 10 mL/kg/min have both a higher predicted morbidity and mortality.¹⁹¹

For patients who either refuse surgery or are deemed medically unfit for surgery, primary radiotherapy for cure can be considered. This approach was evaluated in a meta-analysis of 1 randomized and 35 nonrandomized trials.¹⁹² The studies were heterogeneous, and the 5-year cancer-specific survival ranged between 13% and 39%. The authors concluded that, even in patients with severe emphysema, radiation therapy can be tolerated if careful planning with three-dimensional conformal techniques is undertaken. *Conformal* indicates that the radiation is designed in 3 dimensions to match the shape of the tumor allowing maximal targeting to the tumor with minimal injury to adjacent normal tissue.

More recently, stereotactic body radiation therapy has been introduced as a highly precise and accurate delivery method of highly conformal and dose-intensive radiation to small-volume targets. This method is also referred to as stereotactic ablative body radiotherapy and stereotactic radiosurgery. It is a more aggressive dose intensification than could previously be achieved using conventional radiotherapy methods.¹⁹³

In the Radiation Therapy Oncology Group trial (ROTG 0236), patients with biopsy proven stage I NSCLC deemed medically inoperable received stereotactic body radiation therapy with 60 Gy in three fractions. Primary tumor control of 98%, regional control of 87%, and overall survival of 56% at 3 years were achieved.¹⁹⁴ This study and others (ROTG 0618) have demonstrated a dose-response relationship that favors more intensive regimens with biologically equivalent doses of more than 100 Gy consistently resulting in more than 90% primary tumor control for T1 tumors and overall survival greater than 50%. A meta-analysis demonstrated an overall survival improvement with stereotactic body radiation therapy compared with conventionally fractionated radiation therapy.¹⁹⁵

Stage II

Stage II NSCLC lung cancer is divided into stage IIA and stage IIB. Stage IIA is defined as a T1a-T2aN1M0 and T2bN0M0 disease and stage IIB includes T2bN1M0 and T3N0M0. The 5-year survivals for stage IIA and IIB are 46% and 36%, respectively.

Stage IIA lung cancer is quite uncommon, representing between 1% and 5% of patients treated in several surgical series.¹⁹⁶⁻²⁰¹ Stage IIB cancer may represent up to 15% of surgically resected cases.^{189,196,198,201} For stage IIA and IIB cancer, surgical therapy is the treatment of choice. There is no benefit to postoperative radiotherapy. The value of adjuvant chemotherapy after surgery is discussed later (see “Stage IIIA”) but, in short, adjuvant chemotherapy is recommended for all patients with resected stage II disease. With chest wall invasion (T3N0M0) (eFig. 53-16), an en bloc resection of the tumor and chest wall is the treatment of choice. A specific discussion of the evaluation and treatment of Pancoast tumor is discussed later in the chapter.

The outcome of lung cancer surgery is improved when the surgery is performed at hospitals with a higher volume of procedures.¹⁹⁷ It is also important that the surgery be performed by a thoracic surgeon; when lobectomy is

Figure 53-3 Stage IIIA disease. **A**, CT depicts a primary tumor mass invading the chest wall, resulting in stage IIIA non-small cell lung cancer (NSCLC; T3N2) (arrow). **B**, CT depicts enlarged aortopulmonary lymph node (arrow). **C**, PET with uptake in primary tumor (left image, arrow) and lymph node (right image, arrow).

performed by a thoracic surgeon compared to a general surgeon, mortality is nearly halved.²⁰²

Stage IIIA

Stage IIIA NSCLC represents a heterogeneous group of patients with N2 disease (Fig. 53-3) and includes T3N1 patients. In addition, within the new staging system, patients with T4N0-1 have been down-staged to IIIA from their previous classification.^{33,203}

For carefully selected T4N0-1M0 patients, surgery may be indicated with or without neoadjuvant chemotherapy or neoadjuvant chemoradiotherapy (superior sulcus tumors) (eFigs. 53-17 and 53-18).²⁰⁴ Individuals with T4N0-1 disease due to main carinal involvement have been treated with carinal resection with or without pulmonary resection. Carinal resection carries an operative mortality of 10% to 15% and 5-year survival of approximately 20% in carefully selected series. Patients who are T4N0 solely due to tumor nodules within the ipsilateral nonprimary lobe (eFig. 53-19) have a 5-year survival of around 20% with surgery alone.²⁰⁵

There is substantial debate over what constitutes resectable IIIA (N2) disease. However, there is no debate that T3N1 disease is best treated with surgical resection. At surgery, when a complete resection of the lymph nodes and the primary tumor is possible, some patients are found to have occult N2 metastasis. If so, these patients are best served by a resection of all known disease and then by consideration for adjuvant chemotherapy.^{33,203}

It is less certain how best to treat patients when N2 (single or multiple station) metastases are documented before thoracotomy. The new ACCP guidelines used the groupings of infiltrative stage III (N2/N3) tumors and stage III with discrete N2 involvement. In infiltrative stage III with N2/N3 involvement, the mediastinal nodes can no longer be clearly distinguished and measured (eFig. 53-20). These patients have extensive tumor infiltration in the mediastinum, which partially surrounds the major structures. In patients with infiltrative stage III (N2/N3), good performance score, and minimal weight loss ($\leq 10\%$), the recommended treatment with curative intent is with concurrent chemoradiotherapy.^{33,203}

Two multicenter trials have concluded that concurrent chemoradiotherapy is superior to sequential therapy with chemotherapy followed by thoracic radiotherapy.^{206,207}

Concurrent therapy, however, is associated with a higher rate of severe esophagitis than is sequential therapy. The recommended chemotherapy is a platinum doublet and the most common agents are etoposide and cisplatin.²⁰⁸⁻²¹⁰ Three cooperative group trials of definitive chemoradiotherapy for unresectable stage III had an MST of 19 to 22 months with 2-year survivals of 40% to 45% and a 5-year survival of approximately 20%.

For patients with discrete N2 involvement, the ACCP guidelines recommend that the treatment plan be discussed by a multidisciplinary team. Either definitive chemoradiotherapy or induction therapy followed by surgery is recommended over either surgery or radiation alone. These recommendations were largely influenced by the two cooperative group trials that evaluated the role of surgery in patients with N2 disease.^{208,211} The European trial randomized patients with histologically proven N2 disease to radiotherapy or surgery after initial induction therapy with three cycles of a cisplatin doublet chemotherapy.²¹¹ The MST was 16 months in the surgery arm and 17 months in the radiotherapy arm.²⁰⁶ The 5-year survival in both arms was 16% and 14%, respectively, and was not significantly different. The North American trial also required pathologic proof of N2 disease and randomized patients to completion radiotherapy or surgery after induction of two cycles of etoposide and cisplatin with concurrent thoracic radiotherapy of 45 Gy in 25 fractions over 5 weeks.²⁰⁸ The MST was 24 and 22 months in the surgery and radiotherapy arms, respectively, with 5-year survivals of 27% and 20% (hazard ratio 0.87, $P=0.24$). These survival differences were not statistically significant. However, the PFS favored the surgery arm. A subset analysis in those having only a lobectomy after induction therapy did better than a matched group receiving only chemoradiotherapy. This was an unplanned subset analysis that weakens the strength of this analysis. Accordingly, the role of surgery for stage III with discrete N2 disease has not been definitively answered.

In patients with stage II or IIIA totally resected NSCLC, adjuvant chemotherapy with four cycles of a cisplatin-based doublet chemotherapy is recommended.^{203,212} The *Lung Adjuvant Cisplatin Evaluation* (LACE) meta-analysis evaluated all stages of totally resected disease and observed a 5.4% overall 5-year survival benefit with adjuvant chemotherapy. The benefit was the greatest for patients with stage II and III disease and those with better performance

status. The role of postoperative radiation therapy for patients with totally resected stage III (N2) remains controversial. Local recurrence varies in reports from 20% to 60%. Some nonrandomized trials suggest possible benefit from postoperative radiation therapy.^{213,214} Accordingly, this option should be discussed with fit patients. A randomized phase III *Adjuvant Radiotherapy* (ART) trial is underway to evaluate postoperative radiation therapy in these patients.

Stage IIIB

Stage IIIB is also a heterogeneous group and includes T4N2M0 and any T N3M0 patients. There are no phase III randomized trials to date that demonstrate that neoadjuvant chemoradiotherapy followed by surgery for stage IIIB disease results in prolonged survival compared with chemoradiotherapy alone.²⁰³

Patients with unresectable stage IIIB NSCLC are treated the same as those with unresectable IIIA disease. The MST is generally 19 to 22 months, with a 5-year survival of 10% to 20%. The randomized trials of chemoradiotherapy included both stage IIIA and IIIB disease participants so it is not possible to separate out the survival of stage IIIB patients specifically.^{209,210} Concurrent chemoradiotherapy is recommended for both unresectable stage IIIA and IIIB disease.²⁰³ Trials have evaluated multiple daily fractions of thoracic radiotherapy, but there are no convincing data that hyperfractionated thoracic radiotherapy (the same total dose of radiation therapy split into two treatments in the same day) is superior to standard once-daily treatment.

Stage IV

Stage IV NSCLC is generally considered to be incurable with 5-year survivals of 1% to 3%. The goal of therapy is to try to control the disease and palliate symptoms. Major response rates with current chemotherapy regimens are 10% to 30%. Patients who respond to chemotherapy may gain an additional 3 to 9 months of life on average but eventually relapse and die of their disease. In previous trials in the 1970s and 1980s, patients were randomized to best supportive care or systemic chemotherapy. A meta-analysis evaluated eight of these randomized trials, including more than 700 patients.²¹⁵ Each of these trials used a cisplatin-based chemotherapy versus supportive care. With best supportive care, the MST was 4 months and the 1-year survival was 15%; with chemotherapy, there was an increase in the MST of 1.5 months and an increase in 1-year survival of 10%. In the 1990s, a number of new chemotherapy agents were introduced, including paclitaxel, docetaxel, irinotecan, vinorelbine, and gemcitabine. Phase III trials have incorporated these newer agents in combination with cisplatin or carboplatin.²¹⁶

Trials comparing single-agent chemotherapy to a chemotherapy doublet containing a platinum compound have shown that the chemotherapy doublet is superior. Treatment with three drugs has not been shown to be superior to that with two drugs. Large randomized trials have tried to identify the optimum chemotherapy doublet.²¹⁷⁻²¹⁹ The results were uniformly similar, with response rates of 20% to 30% and MST of 7 to 9 months. No one platinum doublet has been shown to be superior. The chemotherapy combinations did have different toxicity profiles.

Histology influences response to certain chemotherapeutic agents. A large phase III trial randomized patients to cisplatin and pemetrexed or gemcitabine and cisplatin. Whereas there was no difference in the overall survival for the 847 patients with adenocarcinoma, the survival was significantly better with the pemetrexed regimen (MST 12.6 months vs. 10.9 months). Conversely, squamous cell cancers had superior survival with the gemcitabine regimen (MST 10.8 months vs. 9.4 months).²²⁰ The ACCP guidelines recommend that chemotherapy for stage IV NSCLC should be guided by histology. Pemetrexed should be limited to patients with nonsquamous NSCLC.²²¹ In patients with a good performance score, a platinum-based doublet chemotherapy regimen is recommended.

In the Eastern Oncology Group Trial (E4500), patients with nonsquamous histology were randomized to treatment with carboplatin and paclitaxel with or without bevacizumab, a monoclonal antibody that inhibits a vascular endothelial growth factor. Bevacizumab was continued as maintenance therapy after six cycles of therapy in those responding to treatment or with stable disease.^{221a} Patients in the bevacizumab arm had a higher response rate (35% vs. 15%) and better survival (MST 12.3 months vs. 10.3 months; 2-year survival 44% vs. 15%). A meta-analysis of four randomized trials of NSCLC patients treated with bevacizumab demonstrated increased PFS and overall survival in patients treated with combination chemotherapy and bevacizumab than in patients treated with chemotherapy alone.²²² In selected patients with nonsquamous histology and good performance scores, the addition of bevacizumab is recommended. Hemoptysis, uncontrolled brain metastasis, deep venous thrombosis, and anticoagulation treatment are contraindications to using bevacizumab.²²¹

In patients with stable or responding disease whose initial therapy included bevacizumab, maintenance treatment with bevacizumab until progression is generally recommended. For patients with an initial platinum-based doublet chemotherapy and responding or stable disease, maintenance treatment with pemetrexed has been shown to prolong survival.²²¹ A randomized Eastern Oncology Group Trial is currently evaluating maintenance treatment with bevacizumab versus pemetrexed versus the two-drug combination. This is likely to be a definitive study on maintenance therapy.

Targeted Therapy

In 2004, investigators identified activating mutations in the tyrosine kinase domain of *EGFR* that predicted response to novel *tyrosine kinase inhibitors* (TKIs) in selected patients with NSCLC^{223,224} (see Chapter 51). This activating mutation was found to be a “driver” mutation because it was causal in tumor development; the mutation activated EGFR signaling thereby driving and sustaining the tumor. *Driver* mutations, as opposed to the much more common *passenger* mutations, thereby render a tumor vulnerable to blockade of that single pathway.

Multiple studies have demonstrated that the phenotype most associated with response to the EGFR-TKIs, gefitinib and erlotinib, includes adenocarcinoma, never-smoker, female, and East Asian descent. Subsequent reports have shown that these are the groups most likely to harbor the

activating *EGFR* mutations. Emerging data have demonstrated that *KRAS* and *EGFR* mutations are almost always mutually exclusive and that patients with *KRAS* mutations do not respond to *EGFR*-TKIs.²²⁵ Erlotinib has been shown in a phase III trial in previously treated patients with NSCLC to result in superior survival versus placebo (6.7 vs. 4.7 months).²²⁶ On this basis, erlotinib was approved by the U.S. Food and Drug Administration (FDA) for second-line treatment. A phase III trial of gefitinib in second-line therapy failed to show a significant improvement in survival and approval for second-line therapy was withdrawn by the FDA in North America.²²⁷ In a landmark phase III trial in East Asia, patients with untreated stage IV disease were randomized to gefitinib or platinum-based chemotherapy. Of the 437 patient samples tested, 60% were positive for an activating mutation of *EGFR*. This subgroup had a significantly better response and PFS after gefitinib than after chemotherapy. The subgroup negative for mutations responded better and had a better PFS after chemotherapy.²²⁸

Since that key study of first-line treatment with an *EGFR*-TKI or with chemotherapy, there have been multiple additional trials in patients with *EGFR* activating mutations. A meta-analysis of the use of *EGFR*-TKI in a first-line (13 trials) or in a second-line setting (7 trials) observed a PFS advantage (HR 0.43) in those patients with an activating *EGFR* mutation treated with an *EGFR*-TKI in the first-line setting.²²⁹ Results were similar when the *EGFR*-TKI was used in the second-line setting in those with an activating *EGFR* mutation (HR 0.34 for PFS). For patients whose tumor contains an activating *EGFR* mutation, the response rate to an *EGFR*-TKI is 60% to 80% with a median PFS of 9 to 12 months and an overall survival of approximately 2 years.²³⁰ As a result of these and other studies, erlotinib is FDA-approved as first-line treatment of metastatic NSCLC for patients whose tumors have *EGFR* exon 19 deletions or exon 21 (L858R) substitution mutations.

The *anaplastic lymphoma kinase* (*ALK*) fusion gene is the second most common driver mutation for which there is an effective TKI. The efficacy of the first generation *ALK*-TKI, crizotinib, was demonstrated in a phase I study that was expanded and resulted in a rapid FDA approval of the drug. Of 143 patients with stage IV NSCLC with an *ALK* fusion, the objective response rate was 61% and a median PFS was 9.7 months. The estimated 12-month survival was 75% and the MST had not been reached at the time of publication.²³¹

In a randomized phase III trial, advanced stage NSCLC patients with an *ALK* fusion who failed one prior platinum-based treatment were treated with crizotinib (*ALK*-TKI) or single agent pemetrexed or docetaxel.²³² The median PFS was 7.7 months in the crizotinib group compared with 3 months in the chemotherapy group (HR 0.49). The response rate favored crizotinib treatment (65% vs. 20%), even though there was no significant difference in survival between the two treatment arms. The FDA has approved ceritinib for the treatment of NSCLC patients with an *ALK* fusion who were previously treated with crizotinib, to which some cancers develop resistance.^{232a,232b}

The Lung Cancer Mutation Consortium consists of 14 cancer centers in the United States and is sponsored by the National Cancer Institute. These centers have tested more

than 1000 lung adenocarcinomas to look for driver mutations in 10 genes with a goal of determining treatment based on the molecular subtypes.²³³ A driver mutation was detected in 63% of 733 fully genotyped cases. The driver mutations identified were *KRAS* (25%), activating *EGFR* (15%), *ALK* rearrangements (8%), *BRAF* (2%), *HER2* (2%), *PIK3CA* (1%), and *MET* amplification (1%). Results were used to select targeted therapy or targeted therapy trials in 279 patients with a driver mutation (28% of 1007). This study demonstrated the potential for multiplex genomic testing in patients with advanced NSCLC and is certainly the direction for the future.

Recently, joint guidelines by the College of American Pathologists, International Association for the Study of Lung Cancer, and the Association of Molecular Pathology have recommended that all patients with advanced stage adenocarcinomas should be tested for *EGFR* and *ALK* mutations and patients should not be excluded from testing based on clinical characteristics. These results should be used to select patients for targeted therapy with *EGFR*-TKIs or *ALK*-TKIs. Ideally, this testing should be performed before initial treatment of advanced stage lung cancer.²³⁴ In addition to targeted therapy based on mutation analysis, immunotherapy is a promising future direction in therapy for NSCLC. There are several large clinical trials underway using vaccines and checkpoint inhibitors which may provide additional therapeutic options.^{234a}

SMALL CELL LUNG CANCER

SCLC accounts for approximately 15% of all lung cancers. This cell type has the strongest association with cigarette smoking and is rarely observed in a never-smoker. It is the cell type most commonly associated with paraneoplastic syndromes such as the syndrome of *inappropriate (excessive) antidiuretic hormone secretion* (SIADH), ectopic corticotropin secretion, *Lambert-Eaton myasthenic syndrome* (LEMS), and sensory neuropathy.

SCLC usually presents as a centrally located mass in the hilum on chest radiograph (eFig. 53-21) and may be associated with obstructive pneumonia. In 5% or fewer cases, SCLC may present as a solitary pulmonary nodule/mass (eFig. 53-22). SCLC is generally staged according to the Veterans Administration Staging System, and classified as *limited disease* (LD) or *extensive disease* (ED). LD is confined to one hemithorax, the mediastinum, and the ipsilateral supraclavicular lymph nodes, and the disease can be encompassed adequately in a safe radiation portal.²³⁵ ED is any disease spread beyond these limits. Malignant pleural effusion or disease extending to the contralateral supraclavicular or hilar lymph nodes is generally considered to be ED. More recently, it has been proposed that the new TNM staging system (7th edition) should also be used for small cell lung cancer. The clinical stage groupings of I to IV were predictive of overall survival and the findings were validated in a cohort from the Surveillance Epidemiology and End Results registry²³⁶ and the California Cancer Registry.²³⁷ The survival rate for patients with LD with pleural effusions was intermediate between those with ED and LD without pleural effusions. The TNM staging is most helpful in potentially resectable patients with T1-2N0 disease. Accordingly, it would be advisable to use both the TNM for

tumor registries and clinical trials to define patients with minimal disease.

After establishing the histologic diagnosis of SCLC, patients are usually staged with MRI of the brain, CT of the chest (through the adrenal glands), and bone scan or PET. In an evidence-based review of the literature, staging using PET was compared with conventional staging using non-PET imaging. Of 267 patients with LD by conventional imaging, 16% were upstaged by PET. Of 199 patients with ED, PET resulted in 11% being down-staged. In total, staging with PET improves the accuracy of initial staging and radiotherapy planning.²³⁵ If a PET scan is obtained, then a bone scan may be omitted. In the unusual case when SCLC presents as a peripheral nodule, the treatment of choice is surgical resection followed by adjuvant chemotherapy and possibly sequential thoracic radiotherapy. Careful preoperative staging should be performed in these individuals to rule out metastatic disease. Pre-resection mediastinoscopy should also be performed in all patients being considered for resection with curative intent. If there are mediastinal node metastases, then surgery should be abandoned, and the patient treated with concurrent chemoradiotherapy as outlined later. The 5-year survival for peripheral SCLC that is treated with surgery and adjuvant therapy is approximately 40% to 50%.^{238,239} Approximately one third of patients have LD at diagnosis. LD-SCLC has a response rate of 70% to 80% with standard chemotherapy and thoracic radiotherapy (eFig. 53-23), and a complete clinical response of 50% to 60%. In a meta-analysis of trials with chemotherapy alone versus combined chemotherapy and thoracic radiotherapy, survival was significantly better with combined modality therapy. A meta-analysis evaluated the timing of thoracic radiotherapy.²⁴⁰ Early thoracic radiotherapy (<9 weeks from the start of chemotherapy) resulted in a 5.2% increase in 2-year survival. The interval from start of treatment to the end of radiotherapy was also identified as an important predictor of outcome.²⁴¹ Accordingly, data suggest that thoracic radiotherapy should begin early and be completed quickly.²³⁵ Chemotherapy usually consists of a platinum-based regimen. The two most commonly used regimens are etoposide and cisplatin or etoposide and carboplatin. Chemotherapy beyond four to six cycles has not been shown to prolong survival.

The National Comprehensive Cancer Network and the ACCP guidelines recommend treatment with four to six cycles of a platinum-based chemotherapy with either cisplatin or carboplatin plus either etoposide or irinotecan.²³⁵ Multiple trials have evaluated a number of the novel molecularly targeted agents but to date none have shown improved outcomes when added to standard treatment of small cell lung cancer.²⁴² A number of trials evaluating insulin-like growth factor receptor inhibitors, antiangiogenesis, and immunomodulatory drugs are under evaluation.

If a patient with SCLC achieves a complete remission, then there is a 50% chance of development of cranial metastasis within the next 2 years. A meta-analysis of seven randomized trials of *prophylactic cranial irradiation* (PCI) versus no PCI for patients in complete remission reported an observed beneficial effect after PCI, with a 5.4% increase in absolute survival (20.7% vs. 15.3%) at 3 years.²⁴³ The major questions raised by the meta-analysis concern the optimal dose of PCI and the neuropsychological sequelae.

PCI is recommended in patients who achieve a complete remission with initial therapy. PCI has also been shown to result in a survival advantage in patients with ED-SCLC who achieve a complete or partial response to initial therapy.²⁴⁴ PCI at 25 Gy in 10 fractions is the standard dose fractionation used in SCLC.²⁴⁵

When patients relapse after initial therapy, the median survival is 3 to 4 months. There are no cures with second-line therapy. If a patient has been off treatment for 6 months or longer, then it is reasonable to use the same agents that he or she received initially. If initial therapy did not include a platinum agent, then second-line therapy should be with a platinum-containing doublet. Currently, the only drug approved for second-line treatment of SCLC by the FDA is single-agent topotecan.^{235,246} Other single agents such as oral etoposide, paclitaxel, docetaxel, irinotecan, gemcitabine, and amrubicin are active but are not yet approved by the FDA for second-line treatment of SCLC. Amrubicin is commercially available and approved for second-line treatment in Japan but is not available in the United States. No molecularly targeted therapy has been approved for SCLC in either the first-line or second-line setting.

PALLIATIVE CARE

Although much of this chapter is devoted to efforts to cure lung cancer, most patients will eventually succumb to their disease. Although pulmonologists are adept at providing supportive care in the intensive care unit, caring for the ambulatory dying patient with lung cancer requires special consideration (see Chapter 104). There is a vast literature on ambulatory pain management, the use of interventional pulmonary techniques such as tumor ablation and stent placement to relieve malignant airway obstruction (see Chapter 19), and the use of hospice to provide end-of-life care in the home setting. With the tools now available to physicians, patients need not suffer debilitating cough, nausea, dyspnea, or pain. Pulmonologists are encouraged to provide “aggressive palliation” with the same conviction that they provide treatments for critically ill patients in the intensive care unit.²⁴⁷

SPECIAL CONSIDERATIONS IN LUNG CANCER

SUPERIOR SULCUS TUMORS AND PANCOAST SYNDROME

Pancoast syndrome is a constellation of symptoms and signs that include shoulder and arm pain along the distribution of the eighth cranial nerve trunk and first and second thoracic nerve trunks, Horner syndrome, and weakness and atrophy of the hand.²⁴⁸⁻²⁵⁰ The underlying cause is usually local extension of an apical lung tumor located in the superior pulmonary sulcus (Pancoast tumor) (see eFig. 53-17). Pancoast syndrome is present in approximately one third of patients with superior sulcus tumors. The most common cause of this symptom complex is NSCLC; however, SCLC and a number of other types of tumors and infections may rarely present in this manner.²⁴⁸

Figure 53-4 Superior sulcus (Pancoast) tumor. **A**, Frontal chest radiograph shows a mass at the extreme right pulmonary apex. Axial (**B**) and coronal (**C**) enhanced chest CT shows a mass (arrow) at the right apex, arising from the superior sulcus region, identified by the presence of the subclavian artery (arrowheads). Note first rib destruction (double arrowheads, **B**). Right paratracheal lymphadenopathy (*, **C**) is present. (Courtesy Michael Gotway, MD.)

The most common initial symptom is shoulder pain, which is produced by tumor involvement of the parietal pleura, brachial plexus, vertebral bodies, and first, second, and third ribs. The pain may radiate along the upper back or shoulder into the axilla and along the distribution of the ulnar nerve. Patients are commonly treated for arthritis or bursitis of the shoulder for months before the correct diagnosis is determined. Horner syndrome consists of ptosis, miosis, and anhidrosis and is caused by the invasion of the paravertebral sympathetic chain and the inferior cervical (stellate) ganglion.²⁴⁸ The intrinsic muscles of the hands may become weak and atrophied as the tumor progresses. With further extension through the intervertebral foramina, spinal compression and paraplegia may develop.

The chest radiograph may show an apical tumor (Fig. 53-4A), although in some cases, a tumor can be identified only on chest CT (Fig. 53-4B and C; see eFig. 53-18A). If the diagnosis is suspected but the chest radiograph is negative, then a chest CT scan should be obtained (see eFigs. 53-17 and 53-18A). CT also provides additional information about the extent of the tumor (see Fig. 53-4B) and is especially helpful in identifying other pulmonary nodules and mediastinal adenopathy (see Fig. 53-4C). MRI of the chest is considered to be superior for evaluating patients with superior sulcus tumors because of better assessment of invasion through the pleura and subpleural fat, better evaluation of plexus involvement (see eFig. 53-18B and C), and better definition of subclavian vessel involvement.²⁵¹ Magnetic resonance angiography may give the best assessment of vascular invasion of the subclavian vessels. Flexible fiberoptic bronchoscopy is frequently the first diagnostic test for apical tumors and has a diagnostic yield of approximately 50%.²⁵² TTNA has a very high diagnostic yield (>90%) even if the bronchoscopy is nondiagnostic.²⁵³ Superior sulcus tumors are usually staged as T3N0M0 (stage IIB) or higher depending on size of the tumor (T3 or T4) and extent of lymph node involvement. In a large series from M.

D. Anderson, 25% of patients were stage IIB, 22% were IIIA, and 53% were stage IIIB (T4 or N3).²⁵⁴ Some patients who were stage IV at diagnosis were excluded from that report. It is estimated that one third to one half of all superior sulcus tumors have identifiable distant metastasis at diagnosis. In addition to the stage of disease and performance score, other important poor prognostic factors include weight loss and vertebral body or supraclavicular involvement. The presence of N1 or N2 nodal involvement and incomplete resections have a worse prognosis.^{254,255} In patients treated for localized disease (stage IIB or IIIB), the brain is the most common site of relapse.²⁵⁶

In the past, the most common treatment for localized superior sulcus tumors due to NSCLC was preoperative radiotherapy of 30 to 50 Gy followed by resection. This resulted in a 5-year survival of 25% to 35%. The current standard of practice is to perform neoadjuvant chemoradiotherapy followed by resection. This is based on results of the North America Intergroup Trial in which patients with a negative mediastinoscopy were treated with two cycles of etoposide and cisplatin chemotherapy and concurrent thoracic radiotherapy (45 Gy in 5 wk). In the resected specimen, a pathologic complete response or minimal microscopic disease was identified in 66% of patients. The overall survival at 5 years was 44% and, for those with a complete resection, 54%.²⁵⁶ In a phase II trial in Japan, chemotherapy with mitomycin, vindesine, and cisplatin with concurrent thoracic radiotherapy led to a 5-year survival of 56%.²⁵⁷ Although the optimal regimen of treatment has not been proved, a reasonable choice is that used in the U.S. Intergroup Trial study described earlier.

SUPERIOR VENA CAVA SYNDROME

The blockage of blood flow in the SVC results in SVC syndrome.²⁵⁸ Bronchogenic carcinoma (see eFig. 83-1A-D and

Figure 53-5 SVC syndrome. **A**, Facial swelling in a patient with superior vena cava (SVC) syndrome. **B**, The same patient also presented with jagged, blanching, violaceous plaques on the upper chest and abdomen. **C**, Chest radiograph shows a right mediastinal mass in another patient with SVC syndrome. (A and B, From Ratnarathorn M, Craig E: Cutaneous findings leading to a diagnosis of superior vena cava syndrome: a case report and review of the literature. *Dermatol Online J* 17, 2011. Figs. 1 and 2; C, courtesy Michael Gotway, MD.)

Video 83-1) accounts for the vast majority of these cases in older adults.^{259,260} In teenagers and young adults, SVC syndrome is usually due to non-Hodgkin lymphoma (see Fig. 83-2A-D and **Video 83-2**). Patients complain of dyspnea and a sensation of fullness in the head and/or light-headedness when bending over. They may also note facial swelling. Cough, pain, and dysphagia are less frequent symptoms. Physical examination findings included dilated neck veins, a prominent venous pattern on the chest, facial edema, and a plethoric appearance (Fig. 53-5A). The chest radiograph typically shows widening of the mediastinum or a right hilar mass (see Fig. 53-5B). Occasionally, it may be normal. Dilated veins on the anterior chest wall and compression of the SVC (see eFigs. 83-1 and 83-2, and **Videos 83-1** and **83-2**) may be demonstrated with CT with intravenous contrast. SVC syndrome is not generally a medical emergency, and patients should not be treated without a tissue diagnosis. Bronchoscopy or mediastinoscopy can be safely performed in the setting of SVC syndrome.²⁶¹ Because SCLC is chemosensitive, SVC syndrome due to SCLC is best treated with chemotherapy; generally, after treatment, symptoms start to resolve in 5 to 7 days.²⁶² NSCLC is best treated with concurrent chemoradiotherapy (see earlier discussion of treatment of stage IIIA/IIIB NSCLC). If there is a need for immediate relief of SVC obstruction, vascular stenting should be strongly considered. A Cochrane meta-analysis reported that SVC stents relieved obstruction in 95% of cases.²⁶² Stenting has been associated with a complication rate of 3% to 7%.

PARANEOPLASTIC SYNDROMES

Hormonal, neurologic, hematologic, or other remote effects of cancer not related to the direct invasion, obstruction, or metastatic effects of tumor are generally termed *paraneoplastic syndromes*. Paraneoplastic syndromes related to bronchogenic carcinoma develop in 10% to 20% of patients (Table 53-6).

MUSCULOSKELETAL EFFECTS

Clubbing of the digits may be a manifestation of lung cancer or other diseases (see Fig. 16-3). Clubbing may involve the fingers and toes and consists of selective enlargement of the connective tissue in the terminal phalanges. Physical findings include loss of the angle between the base of the nail bed and the cuticle, rounded nails, and enlarged fingertips. Clubbing is an isolated finding and is usually asymptomatic. Nonmalignant causes of clubbing include pulmonary fibrosis, congenital heart disease, and bronchiectasis.

Hypertrophic pulmonary osteoarthropathy (HPO) is an uncommon process associated with lung cancer. HPO is characterized by painful arthropathy that usually involves the ankles, knees, wrists, and elbows and is most often symmetrical. The pain and arthropathy are caused by proliferative periostitis that involves the long bones but may also affect metacarpal, metatarsal, and phalangeal bones. Patients may have clubbing of fingers and toes in addition to the painful arthralgias. The pathogenesis of HPO is uncertain, but it may arise from a humoral agent. For patients who smoke and have a new onset of arthralgias, HPO must be considered. A radiograph of the long bones (i.e., tibia and fibula) usually shows characteristic periosteal new bone formation (Fig. 53-6B). A radionuclide bone scan (see Fig. 53-6C) typically demonstrates diffuse uptake by the long bones. Large cell and adenocarcinoma are the most common histologic types associated with HPO (see Fig. 53-6A). The symptoms of HPO may resolve after thoracotomy, whether the primary cancer is resected or not. For inoperable patients, treatment is with nonsteroidal anti-inflammatory agents. Recently, case reports have observed resolution or marked improvement of symptoms with bisphosphonate treatment.²⁶³

Although still a topic of debate, population-based studies from Scandinavia suggest a frequency of malignancy of 15% to 25% in patients with dermatomyositis-polymyositis.²⁶⁴ The highest risk of malignancy is in the first

Table 53-6 Paraneoplastic Syndromes Associated with Bronchogenic Carcinoma

System	Paraneoplastic Syndrome
Musculoskeletal	Clubbing Hypertrophic osteoarthropathy Polymyositis Osteomalacia Myopathy
Cutaneous	Dermatomyositis Acanthosis nigricans Pruritus Erythema multiforme Hyperpigmentation Urticaria Scleroderma
Endocrinologic	Cushing syndrome Syndrome of inappropriate secretion of antidiuretic hormone Hypercalcemia Carcinoid syndrome Hyperglycemia/hypoglycemia Gynecomastia Galactorrhea Growth hormone excess Calcitonin secretion Thyroid-stimulating hormone
Neurologic	Lambert-Eaton myasthenic syndrome Peripheral neuropathy Encephalopathy Myelopathy Cerebellar degeneration Psychosis Dementia
Vascular/hematologic	Thrombophlebitis Arterial thrombosis Nonbacterial thrombotic endocarditis Thrombocytosis Polycythemia Hemolytic anemia Red cell aplasia Dysproteinemia Leukemoid reaction Eosinophilia Thrombocytopenic purpura
Miscellaneous	Cachexia Hyperuricemia Nephrotic syndrome

2 years after the diagnosis of dermatomyositis-polymyositis. A reasonable approach to cancer surveillance in these patients is a careful history and physical examination, chest radiograph, basic laboratory tests, and age-appropriate cancer screening examinations. Other tests should be based on abnormalities detected during the basic evaluation.

HEMATOLOGIC EFFECTS

Anemia is common in patients who have lung cancer and may be caused by iron deficiency, chronic disease, or bone marrow infiltration. Eosinophilia is more often associated with Hodgkin disease but may also be seen in patients with lung cancer. Production of various cytokines by neoplastic cells may result in eosinophilia, leukocytosis, or thrombocytosis, of which thrombocytosis is by far the most common. Many of the hematologic effects of lung cancer do not lead to clinical sequelae, and specific hormones or antibodies responsible for the effects are typically not found.

The association of deep venous thrombosis and malignancy was described by Trousseau more than a century ago, and lung cancer is the most common malignancy associated with hypercoagulability. The causes of the hypercoagulable state remain poorly understood. One large study documented a clinically significant association of idiopathic thrombosis with the subsequent development of overt cancer; however, other investigators concluded that the literature does not enable firm recommendations about whether to screen for a malignant neoplasm in patients who have unexplained venous thromboembolism.²⁶⁵ Thromboembolism in the patient who has malignancy is often refractory to warfarin treatment, and treatment with *low-molecular-weight heparin* (LMWH) on a long-term basis is likely more effective. In a randomized trial, patients with cancer and deep vein thrombosis, pulmonary embolism, or both were randomized to receive LMWH (dalteparin) subcutaneously once daily or oral warfarin daily for 6 months.²⁶⁶ At 6 months, the probability of recurrent thromboembolism was 9% with dalteparin treatment and 17% with warfarin, a difference that was highly significant. The risks of major bleeding or any bleeding were not different in the two groups. The other advantage of LMWH is that it is not necessary to monitor the anticoagulant effect, except in some patients with renal insufficiency. A recent Cochrane analysis concluded that, for long-term treatment in patients with cancer, LMWH reduced venous thromboembolism events, but not death, as compared with vitamin K antagonists. There was no significant difference in the risk of bleeding²⁶⁷ (see Chapter 57).

HYPERCALCEMIA

Hypercalcemia of malignancy may arise from a bony metastasis, accelerated bone resorption, decreased bone deposition, or increased renal tubular reabsorption of calcium, but, most commonly, is due to secretion by the tumor of a *parathyroid hormone–related protein* (PTHrP) or other bone-resorbing cytokine (see Chapter 95). Lung cancer is the most common solid tumor associated with hypercalcemia, but other cancers also have an association, such as kidney, breast, and head and neck cancer, myeloma, and lymphoma. In one study of 690 consecutive lung cancers, 2.5% of cases had tumor-induced hypercalcemia.²⁶⁸ Squamous cell histology is the most common cell type associated with hypercalcemia, but hypercalcemia does not rule out other lung cancers such as adenocarcinoma or, very rarely, small cell carcinoma. Generally, lung cancer patients with hypercalcemia have advanced disease (stage III or IV) and are unresectable.

Symptoms of hypercalcemia include anorexia, nausea, vomiting, constipation, lethargy, polyuria, polydipsia, and dehydration. Confusion and coma are late manifestations, as are renal failure and nephrocalcinosis. Cardiovascular effects include shortened QT interval, broad T wave, heart block, ventricular arrhythmia, and asystole. Individual patients may manifest any combination of these signs and symptoms in various degrees.

Accelerated bone resorption is caused by activation of osteoclasts by cytokines or PTHrP in most cases. Serum parathyroid hormone levels are usually normal or low, but an elevated level of PTHrP can be detected in the serum in

Figure 53-6 Lung carcinoma and hypertrophic osteoarthropathy. **A**, Frontal chest radiograph shows a left lung malignancy (*arrow*). **B**, Radiograph of the tibia and fibula shows diaphyseal periosteal reaction (*arrowheads*). **C**, Radionuclide bone scan shows fairly symmetric, bilateral lower extremity tracer uptake, consistent with hypertrophic osteoarthropathy. (Courtesy Michael Gotway, MD.)

approximately one half of these patients.²⁶⁸ Cytokines or PTHrP are secreted autonomously by the tumor. Not only does PTHrP cause renal calcium reabsorption, but also it interferes with renal mechanisms for reabsorption of sodium and water, with resultant polyuria. Polyuria and vomiting result in dehydration; decreases in glomerular filtration further aggravate the hypercalcemia.

While most patients who have a serum calcium of 12 to 13 mg/dL or higher are treated, mild elevation of serum calcium may not require treatment, so the decision is based on the patient's symptoms. For patients who have widely metastatic and incurable malignancy, it may be most appropriate to give supportive care only and not treat the hypercalcemia. The average life expectancy in this situation is 30 to 45 days, even with aggressive treatment.²⁶⁹

The four basic goals of treatment are to (1) correct dehydration, (2) increase renal excretion of calcium, (3) inhibit bone resorption, and (4) treat the underlying malignancy. Because of the polyuria, patients with hypercalcemia are

usually volume-depleted. Initial treatment is with intravenous normal saline, using 3 to 6 L/24 hr as tolerated, with careful attention to volume status. Previously, a loop diuretic such as furosemide or ethacrynic acid was added to maximize calcium excretion but has become less commonly used due to the efficacy of the bisphosphonates in inhibiting bone resorption. Thiazide diuretics are not used because they increase calcium reabsorption in the distal tubule. Fluids and diuretics generally result in only a mild decrease of the calcium; additional treatment is needed to inhibit the accelerated bone resorption. The bisphosphonates have a high affinity for bone and inhibit osteoclast activity. Zoledronate, a newer bisphosphonate, is the most effective; the usual dose is 4 mg given intravenously over 15 minutes.²⁷⁰ Normal calcium levels are achieved within 4 to 10 days in 85% of patients and last a median of 30 to 40 days. Adverse effects are generally mild and transient and include fever, hypophosphatemia, asymptomatic hypocalcemia and, occasionally, renal failure. Calcitonin inhibits bone

resorption, increases renal calcium excretion, and has a rapid onset of action, but the duration of action is short lived. Calcitonin is a relatively weak agent and, when used alone, does not usually normalize the serum calcium of patients who have marked hypercalcemia. Use of calcitonin is appropriate when the calcium is greater than 14 mg/dL or needs to be lowered urgently (onset of action is 4 to 6 hours) while waiting for the more effective but slower acting agents to take effect or when relief of bone pain is desired. The effects of calcitonin and bisphosphonates are additive. Tachyphylaxis to calcitonin may be seen 48 hours after administration. Other agents such as gallium nitrate or plicamycin have been used to treat hypercalcemia but have not generally been adopted as first-line therapies because of inconvenience of administration schedules or associated toxicities.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Hyponatremia is noted at the time of presentation in approximately 15% of patients with SCLC and 1% of patients with NSCLC and, in most cases, is due to ectopic production of arginine vasopressin by the cancer cells.²⁷¹ Under normal conditions, antidiuretic hormone (vasopressin) is secreted in the anterior hypothalamus and exerts its action on the renal collecting ducts by enhancing the flow of water from the lumen into the medullary interstitium, thereby concentrating the urine. The criteria for the diagnosis of SIADH include (1) hyponatremia associated with serum hypo-osmolality (<275 mOsm/kg), (2) inappropriately elevated urine osmolality (>200 mOsm/kg) relative to serum osmolality; (3) elevated urine sodium (>20 mEq/L); (4) clinical euolemia without edema; (5) normal renal, adrenal, and thyroid function. The serum uric acid is usually low, and the urine osmolality-to-serum osmolality ratio is frequently greater than 2.

The severity of symptoms is related to the degree of hyponatremia and the rapidity of the fall in serum sodium. In one large series of patients with SIADH, only 27% had signs or symptoms of hyponatremia despite a median sodium of 117 mEq/L (range, 101 to 129 mEq/L). Symptoms of hyponatremia include anorexia, nausea, and vomiting. With a rapid onset of hyponatremia, symptoms caused by cerebral edema may include irritability, restlessness, personality changes, confusion, coma, seizures, and respiratory arrest.

In minimally symptomatic or asymptomatic patients, fluid restriction of 500 to 1000 mL/24 hr is the initial treatment of choice. Conivaptan is an intravenous vasopressin receptor antagonist that has been shown to be useful in correcting hyponatremia but its use is limited to hospitalized patients. The oral vasopressin receptor antagonist tolvaptan is now available for clinically significant hypervolemic and for euolemic hyponatremia (serum sodium < 125 mEq/L or less marked hyponatremia that is symptomatic and has resisted correction with fluid restriction). It should not be used in patients requiring intervention to raise serum sodium urgently to prevent or to treat serious neurologic symptoms.²⁷²⁻²⁷⁴ If further treatment is needed, oral demeclocycline (900 to 1200 mg/day) can be considered. Demeclocycline induces a nephrogenic diabetes insipidus and blocks the action of antidiuretic

hormone on the renal tubule, thereby increasing water excretion. The onset of action varies from a few hours to a few weeks, so this drug is not recommended for acute emergency treatment. Demeclocycline has potential kidney toxicity. In patients who have more severe or life-threatening symptoms (serum sodium < 115 mEq/L), treatment consists of intravenous saline, supplemental potassium, and diuresis with loop diuretics such as furosemide or ethacrynic acid. With severe confusion, convulsions, or coma, it may be appropriate to treat with 300 mL of 3% saline given over 3 to 4 hours in combination with a loop diuretic (saline without a diuretic will not increase the sodium concentration).

Rapid correction of the sodium may have life-threatening consequences, and caution is advised.²⁷⁵ The rate of correction of the sodium is best limited to a maximum of 12 mEq/L/day, until a level of 120 to 130 mEq/L is reached. Faster correction has been associated with the development of central pontine myelinolysis, which may result in quadriplegia, cranial nerve abnormalities that manifest as pseudobulbar palsy, alteration in mental status, and subsequent death. Accordingly, in the course of treating hyponatremia, the serum sodium must be monitored frequently to ensure that correction is not too rapid. For patients with SIADH due to SCLC, treatment with chemotherapy should be initiated as soon as possible and is likely to result in improvement in the hyponatremia within a few weeks. After an initial response to chemotherapy, SIADH may recur when the tumor relapses.

ECTOPIC CORTICOTROPIN SYNDROME

Ectopic production of corticotropin or corticotropin-releasing hormone with associated Cushing syndrome has been identified in patients with SCLC, carcinoid tumor (lung, thymus, or pancreas), and neurocrest tumors such as pheochromocytoma, neuroblastoma, and medullary carcinoma of the thyroid.²⁷⁶ Of those with ectopic corticotropin secretion, SCLC accounts for 75% of cases, although Cushing syndrome develops in only 1% to 2% of patients with SCLC. Cushing syndrome is seldom caused by NSCLC.

Classic features of Cushing syndrome include truncal obesity, striae, rounded (moon) facies, dorsocervical fat pad (buffalo hump), myopathy and weakness, osteoporosis, diabetes mellitus, hypertension, and personality changes. However, the rapid growth of SCLC means that patients are more likely to present with edema, hypertension, and muscular weakness than with the classic features of Cushing syndrome. Hypokalemic alkalosis and hyperglycemia are usually present. Patients with SCLC and Cushing syndrome appear to have shortened survival compared to those without the syndrome, perhaps because of more frequent opportunistic infections.

The best screen for Cushing syndrome is the 24-hour urine free cortisol measurement. Elevation of cortisol production, lack of suppression with high-dose dexamethasone, and plasma corticotropin levels greater than 200 pg/mL (40 pmol/L) are highly suggestive of ectopic corticotropin as the cause of Cushing syndrome in the absence of a pituitary adenoma. The plasma level of corticotropin is elevated in many, but not all, patients.

Treatment of Cushing syndrome due to ectopic corticotropin has included adrenal enzyme inhibitors such as metyrapone, aminoglutethimide, and ketoconazole, given alone or in combination. Ketoconazole given orally at a dosage of 400 to 1200 mg/day or metyrapone 250 to 750 mg three times per day may control hypercortisolism within a few days to weeks, but the response is variable.²⁷⁷ Dose adjustments are based on achieving normal urinary free cortisol levels or morning plasma cortisol levels of 7 to 11 µg/mL. Symptomatic hypoadrenalism may result from treatment, and some authorities recommend a replacement dose of glucocorticoid when an enzyme inhibitor is started. When Cushing syndrome arises from SCLC, it is advisable to proceed with appropriate chemotherapy and carefully watch for superimposed infections, as for any patient who is receiving high-dose corticosteroids. Cushing syndrome related to a bronchial carcinoid or thymic carcinoid is best treated by surgical resection of the tumor.

NEUROLOGIC EFFECTS

The paraneoplastic neurologic syndromes associated with lung cancer, mostly small cell type, are variable and include LEMS, subacute sensory neuropathy, encephalomyelopathy, cerebellar degeneration, autonomic neuropathy, retinal degeneration, and opsoclonus/myoclonus.²⁷⁸ The frequency of any of these neurologic syndromes in SCLC is approximately 5%, and neurologic symptoms may precede the diagnosis by months to years.^{279,280} Most patients with SCLC who have an associated paraneoplastic syndrome have LD-SCLC that may or may not be obvious on initial evaluation. Careful radiographic evaluation of the lungs and mediastinum is indicated in a smoker who has a suspected paraneoplastic neurologic syndrome. In this setting, even subtle abnormalities of the mediastinum require a biopsy. PET may help identify an occult lesion and facilitate biopsy confirmation of the diagnosis.^{281,282} Many reports have suggested that patients with paraneoplastic neurologic syndromes have a better prognosis than those without the paraneoplastic syndromes with similar stage and histology.

These paraneoplastic neurologic syndromes are thought to be immune-mediated, based on the identification of a number of antibodies in the serum that react with both the nervous system and the underlying cancer.²⁷⁸ However, not all patients with paraneoplastic syndromes have identifiable antibodies in their serum. The literature is confusing because of different names employed by various investigators. The anti-Hu antibody is the same as *antineuronal nuclear antibody type 1* (ANNA-1), and the anti-Ri antibody is identical to ANNA-2. Both of these antibodies, but predominantly anti-Hu, have been associated with SCLC. Anti-Hu is an IgG antibody found in the sera and cerebrospinal fluid and binds to the nuclei of all neurons in the central and peripheral nervous system, including the sensory and autonomic ganglia, the myenteric plexus, and cells of the adrenal medulla. Such antibodies should not be confused with the anti-Purkinje cell antibody (anti-Yo), which is characteristically found in patients who have subacute cerebellar degeneration as a manifestation of gynecologic malignancy or breast cancer. The CRMP-5 antibody, known as anti-CV-2, has also been associated with SCLC and thymomas.²⁷⁸

In a review of 162 sequential patients who had elevated anti-Hu (ANNA-1), 142 (88%) were proved to have cancer, 132 of whom had SCLC.²⁸⁰ In 97% of these cases, the neurologic syndrome preceded the diagnosis of SCLC, usually by less than 6 months but, in 20%, by more than 6 months. Of special note is that 90% of cases had disease limited to the lung or to the lung and mediastinum (LD-SCLC). In a report from Europe, 144 patients of 200 with anti-Hu antibodies had a tumor in the chest.²⁷⁹ Of these, 111 were proved to be SCLC. In one large series, ANNA-1 antibodies were identified in 16% of all patients with SCLC. These antibodies were associated with limited-stage disease, complete response to therapy, and longer survival compared with patients who had SCLC and no ANNA-1 antibody. These neurologic syndromes seldom improve with treatment, so the goal is to prevent progression by starting treatment of the underlying tumor as soon as possible.

Less common manifestations of neurologic paraneoplastic syndromes are orthostatic hypotension and intestinal dysmotility. The gastrointestinal symptoms may present as nausea, vomiting, abdominal discomfort, or altered bowel habits suggestive of intestinal pseudo-obstruction. Many of these patients present with gastrointestinal symptoms and significant weight loss before the diagnosis of SCLC.

LEMS is characterized by proximal muscle weakness, hyporeflexia, and autonomic dysfunction.^{283,284} Cranial nerve involvement may be present and does not differentiate LEMS from myasthenia gravis. LEMS has been strongly associated with antibodies directed against P/Q-type presynaptic *voltage-gated calcium channels* (anti-VGCC antibodies) of peripheral cholinergic nerve terminals. These anti-VGCC antibodies, identified in more than 90% of patients with LEMS, block the normal release of acetylcholine at the neuromuscular junction. (In contrast, myasthenia gravis is associated with anti-acetylcholine receptor antibodies, which are present in approximately 90% of myasthenic patients.)

Of patients with LEMS, malignancy is present in approximately half and, of the cancers, SCLC is by far the most common. And yet, when SCLC patients are studied prospectively, LEMS is uncommon. In a recent study of 63 patients with SCLC examined prospectively, only 3% had clinical and electrophysiologic signs of LEMS, 8% had elevated anti-VGCC antibodies, and 26% had other neurologic symptoms unrelated to LEMS.²⁸⁵ The diagnosis of LEMS is based on characteristic electromyographic findings that show a small amplitude of the resting compound muscle action potential and facilitation with rapid, repetitive, supramaximal nerve stimulation or after brief exercise of the muscle. A single-fiber electromyogram is optimal for making the diagnosis. LEMS is the predominant paraneoplastic neurologic syndrome that may improve with successful treatment of the associated lung cancer. The use of acetylcholinesterase inhibitors is of limited benefit in LEMS.²⁸⁶ However, diaminopyridine, which enhances the release of acetylcholine, has been used with sustained improvement over months in the majority of patients with LEMS with or without cancer.²⁸⁷

Opsoclonus consists of rapid involuntary eye movements that are conjugate in vertical and horizontal directions. In patients with SCLC, NSCLC, or other solid tumors, it is frequently associated with myoclonus. While the

anti-Hu antibody has been identified in patients with SCLC and opsoclonus/myoclonus, the syndrome of opsoclonus/myoclonus is the primary presentation of paraneoplastic cerebellar degeneration associated with anti-Ri antibodies.^{288,289}

Key Points

- Lung cancer currently claims more lives than breast, colon, and prostate cancer combined and is the number-one cancer killer of both men and women in the United States and worldwide.
- Routine screening for lung cancer with low-dose CT scanning is now recommended for certain at-risk groups.
- Accurate staging of lung cancer is critical because treatment strategies and outcome vary significantly by stage. The pulmonologist is uniquely positioned to stage lung cancer appropriately.
- In general, for non-small cell lung cancer, early lung cancer (stage I) is treated with surgery alone, stage II lung cancer is treated with surgery followed by adjuvant chemotherapy, locally advanced lung cancer (stage IIIA and B) is treated with a combination of chemotherapy and radiotherapy, and metastatic disease (stage IV) is treated with chemotherapy alone.
- For small cell lung cancer, localized disease (disease within one hemithorax that can be encompassed in a radiation port) is treated by chemoradiotherapy; extensive disease is treated with chemotherapy alone.
- A certain subgroup of lung cancer patients with an activating mutation of the tyrosine kinase domain of the epidermal growth factor receptor respond to tyrosine kinase inhibitors such as erlotinib or gefitinib. Patients with an *EML4-ALK* translocation can respond to the tyrosine kinase inhibitor, crizotinib.
- Therapy targeted to block driver mutations is a major advance in the approach to lung cancer therapy and will be the focus for developing new treatments for lung cancer.

eFIGURE IMAGE GALLERY

Figure 53-1 Lung carcinoma staging: false-positive CT and true-negative PET mediastinal lymph node assessment. **A**, Axial chest CT shows a right upper lobe primary lung malignancy (*arrow*) and a mildly enlarged right paratracheal lymph node (*arrowhead*). Axial (**B**) and coronal (**C**) PET images show intense metabolic activity within the right upper lobe neoplasm (*arrows*) but lack of tracer uptake in the right paratracheal node region (*circle, B and C*), suggesting no tumor involvement in the latter location. Surgical resection confirmed the right paratracheal lymph nodes were free of tumor. (Courtesy Michael Gotway, MD.)

Figure 53-2 Lung carcinoma staging: false-positive CT and true-negative PET mediastinal lymph node assessment. **A**, Axial chest CT shows an enlarged aortopulmonary window lymph node (*arrow*) in a patient with a left upper lobe primary lung malignancy, raising the possibility of N2 disease. **B** and **C**, Axial fused PET images show intense metabolic activity within the left upper lobe lesion (*arrow, B*), but no significant tracer accumulation within the aortopulmonary window lymph node (*arrowhead, C*). The aortopulmonary window lymph nodes were free of malignancy at pathologic analysis following surgical resection. (Courtesy Michael Gotway, MD.)

Figure 53-3 Lung carcinoma staging: false-negative CT and true positive PET mediastinal lymph node assessment. **A**, Axial chest CT shows a peripheral lingular lobulated nodule (*arrow*) representing pulmonary adenocarcinoma. **B**, Axial fused PET image shows intense metabolic activity within the lingular neoplasm (*arrow*). **C** and **D**, Axial unenhanced chest CT shows normal-sized left peribronchial (*arrow*, **C**) and mediastinal (*arrow*, **D**) lymph nodes. **E** and **F**, Axial fused PET images show intense metabolic activity within these lymph nodes (*arrows*). Malignant infiltration of the lymph nodes was shown at biopsy. (Courtesy Michael Gotway, MD.)

eFigure 53-4 Lung carcinoma staging: malignant pleural disease. **A** and **B**, Axial enhanced chest CT in a patient with primary lung malignancy shows features of malignant pleural disease: circumferential, nodular pleural thickening (*arrowheads*). Right paratracheal lymphadenopathy (*arrow*) is present. **C** and **D**, Axial fused PET images show tracer accumulation within both the pleural malignancy (*arrowheads*) and right paratracheal lymph node (*arrow*). (Courtesy Michael Gotway, MD.)

eFigure 53-5 Lung carcinoma staging: malignant pleural disease/dry pleural dissemination. A, Axial chest CT shows nodular thickening of the right major fissure (*arrows*). **B,** Image from video-assisted thoracoscopic surgery shows numerous pleural nodules (*arrows*). (Courtesy Michael Gotway, MD.)

Figure 53-6 False-positive PET in the assessment of suspected lung cancer in a patient with a solitary pulmonary nodule. Axial chest CT shown in soft tissue (**A**) and lung (**B**) windows shows a lobulated, noncalcified right upper lobe nodule (*arrows*). Coronal fused (**C**) and whole-body (**D**) PET images show significant tracer accumulation within the nodule (*arrowheads*), suggesting possible neoplasm. Biopsy revealed *Mycobacterium scrofulaceum*. (Courtesy Michael Gotway, MD.)

Figure 53-7 False-negative PET in the assessment of suspected lung cancer in a patient with a solitary pulmonary nodule: limitations due to low metabolic activity malignancy and spatial resolution. **A**, Fused PET image shows lack of significant tracer accumulation within a lobulated left upper lobe nodule (arrow). **B**, Axial chest CT shown in lung windows, performed near the time of the PET scan, shows an indeterminate lobulated left upper lobe nodule. **C** and **D**, Axial chest CT scans obtained 3 and 6 months, respectively, following **A** and **B** show growth in the left upper lobe nodule. Biopsy subsequently confirmed primary lung malignancy. Lack of significant accumulation of tracer at PET imaging, even though the nodule exceeded 1 cm in size, was the result of low metabolic activity within this malignant nodule. Axial chest CT (**E**) and axial fused PET images (**F**) in a patient with primary pulmonary malignancy show a small right base nodule (arrows). This small nodule shows no significant tracer accumulation at PET. The lesion was followed with serial chest CT and subsequently showed growth. Primary pulmonary malignancy was ultimately proven at biopsy. (Courtesy Michael Gotway, MD.)

eFigure 53-8 Positive impact of PET on lung carcinoma: stage migration from stage III to stage IV classification. **A** and **B**, Coronal whole-body fused PET images in a patient with a left upper lobe pulmonary malignancy (*large arrow, B*) show ipsilateral mediastinal lymph node involvement (*white arrowhead, B*) and an unsuspected isolated contralateral rib metastasis (*small arrow, A*) and brain metastasis (*black arrowhead, B*). (Courtesy Michael Gotway, MD.)

eFigure 53-9 Extrathoracic metastatic disease from lung carcinoma shown at CT. **A**, Caudal image from enhanced chest CT shows bilateral cystic adrenal metastases (*arrows*). **B**, Enhanced neck CT shows an avidly enhancing left parotid nodule, proven on biopsy to reflect metastatic lung carcinoma. **C**, Contrast-enhanced axial brain CT shows a peripherally enhancing brain metastasis (*arrow*) with surrounding vasogenic edema. (Courtesy Michael Gotway, MD.)

eFigure 53-10 Lung cancer staging with PET: adrenal metastasis. Coronal PET shows a medial left lung malignancy (*arrow*) with an isolated right adrenal metastatic focus (*arrowhead*). (Courtesy Michael Gotway, MD.)

eFigure 53-11 Lung cancer staging with PET: hepatic metastasis. Coronal (**A**), axial (**B**), and sagittal (**C**) PET imaging shows a left upper lobe pulmonary malignancy (*arrow*, **A**) and ipsilateral mediastinal lymph node involvement (*arrowhead*) associated with an isolated hepatic metastatic focus (*arrowheads*, **B** and **C**). (Courtesy Michael Gotway, MD.)

eFigure 53-12 Lung cancer staging with PET: osseous metastasis. Axial PET image shows a medial left lung malignancy (*black arrow*) associated with a vertebral body metastatic focus (*white arrow*). (Courtesy Michael Gotway, MD.)

eFigure 53-13 Transthoracic percutaneous lung biopsy for the diagnosis of pulmonary malignancy. Axial chest CT image acquired during a percutaneous biopsy procedure. The biopsy needle (*arrowheads*) has been advanced to biopsy a nodule (*arrow*). (Courtesy Michael Gotway, MD.)

eFigure 53-14 T staging for primary pulmonary malignancy. **A**, T1a lung carcinoma: 8-mm lobulated nodule (*arrow*) in the inferior right middle lobe, completely surrounded by lung. **B**, T2a lung carcinoma: 2.8-cm spiculated left upper lobe nodule (*arrow*), completely surrounded by lung parenchyma, greater than 2 cm away from the carina, and without chest wall or parietal pleural invasion. (Courtesy Michael Gotway, MD.)

eFigure 53-15 T staging for primary pulmonary malignancy: locally restricted disease. T2a lung carcinoma: 3.8 cm left upper lobe spiculated mass, completely surrounded by lung parenchyma, greater than 2 cm away from the carina, and without chest wall or parietal pleural invasion (**A**), and 4.8 cm right upper lobe mass, completely surrounded by lung parenchyma, greater than 2 cm away from the carina, and without chest wall or parietal pleural invasion (**B**). (Courtesy Michael Gotway, MD.)

eFigure 53-16 T staging for primary pulmonary malignancy: chest wall invasion. **A**, Axial chest CT displayed in bone windows shows a large right upper lobe mass with clear erosion of the internal cortex of the rib (*arrowheads*). **B** and **C**, Axial and sagittal enhanced chest CT shows an avidly enhancing subpleural left upper lobe mass extending into the soft tissues of the chest wall (*arrows*). (Courtesy Michael Gotway, MD.)

eFigure 53-17 Superior sulcus anatomy. Axial (A–C) and coronal (D–F) enhanced chest CT through the upper thorax shows the region of the superior sulcus. A–C, Axial enhanced chest CT shows the region of the superior sulcus, extending from the inferior neck superiorly and bounded by the first rib inferiorly and vertebral body medially, and containing structures such as the brachial plexus, stellate ganglion, apical pleura and Sibson fascia, subclavian vein, and subclavian artery (*arrowheads*). (Courtesy Michael Gotway, MD.)

eFigure 53-18 Primary pulmonary malignancy arising in the superior sulcus. **A**, Axial enhanced chest CT shows a mass (*) in the superior sulcus. The region of the superior sulcus on axial CT can be readily and quickly identified when the subclavian artery (*arrowheads*) and first rib (*arrow*) are seen. Coronal T2-weighted (**B**) and T1-weighted (**C**) MRI shows the right upper lobe mass (*arrows*) extending cranially into the neck soft tissues, involving the brachial plexus. (Courtesy Michael Gotway, MD.)

eFigure 53-19 T staging for primary pulmonary malignancy: locally advanced disease. Axial chest CT shows a large primary pulmonary malignancy (*arrowheads*) in the superior segment of the right lower lobe, with a separate tumor nodule in the right upper lobe (*arrow*) (an ipsilateral nonprimary lobe), consistent with T4 disease. (Courtesy Michael Gotway, MD.)

eFigure 53-20 Infiltrating lymphadenopathy versus discrete lymphadenopathy. **A**, Axial enhanced chest CT at the level of the carina shows confluent soft tissue with areas of low attenuation (*double arrowheads*) occupying the right paratracheal and subcarinal spaces, extending toward the right peribronchial region. **B** and **C**, Axial enhanced chest CT shows discretely enlarged lymph nodes in the right paratracheal space (station 4R) (*arrow*, **B**), left tracheobronchial angle (station 4L) (*, **B**), aortopulmonary window region (station 5) (*arrowhead*, **B**), and subcarinal space (station 7) (*, **C**). (Courtesy Michael Gotway, MD.)

eFigure 53-21 Small cell carcinoma: typical imaging appearance. **A**, Frontal chest radiograph shows increased density and enlargement of the left hilum (*arrow*). Coronal (**B** and **C**) and axial (**D**) enhanced chest CT shows confluent soft tissue surrounding and narrowing the left pulmonary artery (*arrowheads*, **B** and **C**) and extending into the mediastinum. (Courtesy Michael Gotway, MD.)

eFigure 53-22 Small cell carcinoma presenting as a solitary pulmonary nodule. **A**, Axial chest CT shows a lobulated peripheral right upper lobe nodule. Appearance suggests pulmonary malignancy, especially adenocarcinoma. **B**, Fused axial PET shows intense metabolic activity within the nodule. Biopsy revealed small cell lung carcinoma. (Courtesy Michael Gotway, MD.)

eFigure 53-23 Small cell carcinoma: treatment response. **A**, Axial enhanced chest CT shows confluent left hilar (*arrow*) and mediastinal (*arrowhead*) lymphadenopathy, proven to represent small cell carcinoma. **B**, Axial enhanced chest CT following therapy shows marked regression in the confluent lymphadenopathy. (Courtesy Michael Gotway, MD.)

General Therapeutic Management

INTRODUCTION

Rare lung tumors are defined as lung tumors with low prevalence and unusual histology. Overall, these tumors account for less than 1% of all primary lung tumors, whereas they correspond to more than 100 different histologic, clinical, radiologic, and prognostic entities.¹⁻⁴ Some rare lung tumors are specific to the lung, whereas others represent tumors more frequently found in other organs that are only rarely detected in the lungs. It is estimated that about 60% of rare primary pulmonary tumors correspond to benign and low-grade lesions and that 40% are malignant.^{1,2} The rare tumors are characterized by their low incidence, but also by poor clinical and imaging descriptions, by the low number of experienced specialists for each tumor subtype, and by the limited amount of specific therapeutic data. Recognition of rare lung tumors relies on characteristic clinical and radiologic signs, on a modified diagnostic and imaging strategy, and on the determination of their primary or secondary nature. Interestingly, some of the rare lung tumors may have a propensity to mimic lung carcinoma as well as benign orphan lung diseases, because they may share clinical, imaging, pathologic, and even molecular features.^{4,5}

Pseudotumors have further been described in the thorax, historically referring to any pseudoneoplasm, but currently restricted to a specific heterogeneous group of diseases characterized by circumscribed fibrous tissue associated with inflammatory and myofibroblastic cells.⁵⁻⁷ Among those, borderline neoplastic/non-neoplastic disorders have been identified, such as inflammatory myofibroblastic tumor with clonal proliferation, thus emerging as a true neoplasm.⁵⁻⁷ Other rare pulmonary disorders are emerging as borderline neoplastic/non-neoplastic disorders, which require multidisciplinary expertise both in the field of

orphan pulmonary diseases and in thoracic oncology, including, for example, amyloidosis or Langerhans cell histiocytosis.

Here our objective is to provide the reader with a practical overview of these disorders. Selected lesions of special interest with relatively high incidence are discussed to illustrate specific issues regarding the overall diagnostic and therapeutic management of rare malignant primary pulmonary tumors and borderline entities. In a closely related chapter, Chapter 56, some of the same entities are discussed when they have overlap between benign and malignant behavior.

CHARACTERIZATION OF RARE LUNG TUMORS

Although accounting for less than 1% of lung malignancies, rare lung tumors correspond to a large array of histopathologic, clinical, radiologic entities.¹⁻⁴ Prevalence may also range from merely uncommon lesions, such as carcinoids, which account for 0.15% of primary lung tumors, to extremely unusual tumors, such as primary pulmonary melanoma, with fewer than 50 reported cases.^{8,9} Overall, the most frequent rare malignant primary lung tumors are, in decreasing order of frequency: carcinoid, *mucosa-associated lymphoid tissue* (MALT) lymphoma, and pneumoblastoma.^{1,10}

Most rare lung tumors develop from orthotopic tissues, constitutive of the normal lung parenchyma, and from hematopoietic tissues,^{1,2} whereas tumors derived from ectopic tissues, including melanoma and meningioma, are more uncommon.¹¹ Some rare tumor subtypes, such as *lymphomatoid granulomatosis* (LG), arise specifically

within the lung, whereas others, such as blastomas and perivascular epithelioid cell tumors, arise in many different tissues of the body including the lung and are infrequent wherever they are located. Furthermore, some primary tumors that are uncommon within the lung may be frequent in other locations, including lymph node lymphomas and soft tissue sarcomas, which present with specific histopathologic differentiation when originating in the lung, such as MALT lymphoma and angiosarcoma, respectively.¹

From a clinical point of view, the hallmarks of rare lung tumors may be, more than their actual low frequency, the absence of comprehensive clinical data, the low number of specialized groups for the care of each tumor subtype, and the lack of specific therapeutic recommendations. More than 90% of rare lung tumor observations are published as case reports or small series including fewer than five patients.^{1,7} Currently, only carcinoids and large cell neuroendocrine carcinoma, as the most frequent of the rare tumor subtypes, have been characterized regarding their clinical, therapeutic, and prognostic features in large retrospective and prospective studies.¹²⁻²⁰

Patients with rare lung tumors, like many patients with cancer, tend to go through several stages of grief, including depression, uncertainty, hope, disappointment, and in most cases, physical degradation and social isolation. The rarity of the tumor may also enhance these feelings, owing to the relative lack of information and the increased feeling of isolation, the geographic disparity in access to specific care, the longer duration of the pretherapeutic workup, the involvement of multiple specialists, a feeling of injustice especially in young and never-smoking patients, and the complex management undertaken in a state of uncertainty.²¹ As a result, patients with rare lung tumors may not receive equal care and some may feel “orphaned,” being incompletely integrated in the process of care of patients with the more frequent bronchogenic carcinoma.

PRIMARY PULMONARY LYMPHOMA AND OTHER LYMPHOPROLIFERATIVE DISEASES

Primary pulmonary lymphoma is defined as a lymphoma affecting one or both lungs, without evidence of extrapulmonary involvement or bone marrow disease at the time of diagnosis and during the subsequent 3 months.²²⁻²⁴ For clinicians, pulmonary lymphomas associated with small-size satellite mediastinal and/or systemic nodes are also regarded as originating from the lung.²³⁻²⁷ Even including these tumors, primary pulmonary lymphomas are rare, representing 0.4% of all lymphomas.²² The most frequent subtypes are MALT-type lymphoma and LG. Other subtypes are found only in immunocompromised patients (eFigs. 90-33 through 90-37, 91-16, and 91-17). Primary pulmonary lymphoproliferative disorders may present with a wide range of radiologic features, mimicking organizing pneumonia, interstitial diseases, or lung cancer.

MUCOSA-ASSOCIATED LYMPHOID TISSUE LYMPHOMA

Pulmonary MALT lymphoma is referred to as nodal marginal-zone B-cell lymphoma, with similar cytopathologic features to other MALT lymphomas, especially gastric lymphoma.²⁸ These low-grade lymphomas account for 70% to 90% of primary pulmonary lymphomas. At pathologic examination, MALT lymphoma appears as a diffuse infiltrate of small monomorphic lymphoid cells, with a typical lymphangitic growth pattern spreading along the broncho-vascular bundles and interlobular septa, and forming solid nodules that fill the alveolar spaces and obliterate the normal lung architecture (Fig. 54-1C and D). Immunohistochemistry forms the basis of the subtype classification, with the expression of the pan-B-markers CD20 and CD79 and the absence of staining for CD5 and CD10.^{28,29} The proliferation is monotypic, with surface and/or cytoplasmic expression of *immunoglobulin* (Ig) M and, less frequently, IgG and IgA (see Fig. 54-1E and F). Light chain restriction can be detected in the plasmacytic component using flow cytometry. MALT lymphomas are associated with unique chromosomal translocations, such as the t(11;18)(q21,q21) resulting in a fusion of the *API2* and *MALT1* genes, the t(1;14) (p22;q32) involving the *BCL10* and *IGH* genes—which is overall much less frequent, more specific to lung locations, and never found in high-grade lymphoma—and the t(14;18)(q32;q21) involving the *IGH* and *MALT1* genes.³⁰⁻³² The precise mechanisms leading to the development of these translocations remain unknown, but they all appear to result in an inhibition of apoptosis and a survival advantage to the cells. In cases with the t(1;14) (*BCL10/IGH*) translocation, immunohistochemistry on paraffin-embedded tissues can detect the strong nuclear overexpression of BCL10, thought to have prosurvival functions. Amplification of the *IGH* gene from paraffin-embedded or cytologic samples with *polymerase chain reaction* (PCR)-based assays was demonstrated to be a reliable method to detect monoclonality in more than 60% of MALT lymphomas.³⁰⁻³²

Contrary to extrapulmonary MALT lymphomas, for which a strong relationship has been established with chronic bacterial inflammation related to *Helicobacter pylori* in the stomach and to *Chlamydia psittaci* in the ocular adnexa, no chronic infectious condition has been associated with pulmonary MALT lymphoma, although concurrent evolution with chronic hepatitis C has been described. However, MALT is absent in the normal bronchial tree and is thought to develop only after long-term inflammation secondary to smoking or to an autoimmune condition.

MALT lymphoma has mainly been observed in patients older than 45 years, with a slight male predominance, but it may also arise in younger patients with underlying immunosuppression, especially related to *human immunodeficiency virus* (HIV) infection, or with inflammatory conditions such as Sjögren disease or rheumatoid arthritis, or in association with *Epstein-Barr virus* (EBV) infection.^{22-27,33,34} Less than 50% of patients are symptomatic, with nonspecific symptoms including cough, dyspnea, and chest pain.^{23,25,26} Unlike the situation with other lymphomas, systemic signs such as fever, swelling, and weight loss are uncommon. Association with IgM or IgG blood monoclonal

Figure 54-1 Primary pulmonary mucosa-associated lymphoid tissue lymphoma. Chest radiograph (A) and chest CT (B) show a focus of consolidation in the right lower lobe that persisted despite prolonged antibiotic therapy. C, Pathologic examination of surgical biopsy showed proliferation of small-size lymphoid cells infiltrating the bronchial wall. Note a bronchial epithelium encased by destructive lymphoid proliferation (arrow). D, At high magnification, lymphoplasmacytic-like cells of the marginal zone lymphoma are associated with an amyloid deposit (arrow). E, With immunoglobulin (Ig) lambda light chain immunostaining, there is a predominance of lambda chain plasma cells (lambda chain restriction; arrow). F, With Ig mu heavy chain immunostaining, there is a predominance of IgM type in plasmacytic and plasma cells (arrow). (C, H&E stain; original magnification $\times 40$. D, Original magnification $\times 100$. E and F, Original magnification $\times 40$.)

gammopathy is observed in 30% of cases. MALT lymphoma exhibits three imaging patterns on chest radiography and computed tomography (CT), which are challenging for differential diagnosis: (1) the most frequent and suggestive is the “pneumonia-like” alveolar consolidation with air bronchograms (see Fig. 54-1A and B) that is typically localized in the middle lobe; (2) a “tumor-like” appearance with a solitary circumscribed nodular opacity (30% of cases) (eFig. 54-1) and possible central air bronchogram; and (3) the “infiltrative” pattern with diffuse poorly defined ground-glass opacities (eFig. 54-2), assumed to represent early-

stage disease before tumor cells invade alveolar spaces.^{22-27,35} The combination of a nodular opacity with peripheral peribronchovascular ground-glass attenuation halo is frequent. Pleural effusion is unusual.

About a third of MALT lymphomas are multifocal at the time of diagnosis, a presentation that may hamper the determination of the primary site.³⁵⁻³⁶ Pulmonary MALT lymphomas are associated with tumor locations in the gastric mucosa in 10% to 20% of patients and in the bone marrow in 15% to 20% of patients. Gastroscopy and bone marrow biopsy are then frequently performed as a

pretreatment workup. ¹⁸F-fluorodeoxyglucose (FDG) positron emission tomography (PET) scanning may not be sensitive enough in MALT lymphoma to exclude extrathoracic disease.^{23,37} The Ann Arbor staging system, although not designed for extranodal lymphoma, may be applied in pulmonary MALT lymphoma, which would be staged as IE (one site, extranodal) in case of lung unilateral or bilateral involvement, and IIE (two sites, both above the diaphragm, extranodal) in case of hilar or mediastinal lymph nodes.

The diagnosis often requires a surgical lung biopsy, because cytologic examination of bronchoalveolar lavage or fine-needle biopsy may show the CD20-positive B-cell infiltration but fail to exclude differential diagnoses, such as reactional lymphoid proliferation, follicular bronchiolitis, or lymphoid interstitial pneumonia. *MALT1* gene rearrangements may be diagnosed on bronchoalveolar lavage.^{31,32}

Therapeutic options are based on the degree of tumor extension. Surgical resection ensures both the diagnosis and the treatment of nodular lesions. In asymptomatic patients, a watch-and-wait attitude may be preferred to aggressive treatment. More advanced MALT lymphoma requires more aggressive management, and several options have been described, from resection to radiotherapy, or single-agent chemotherapy with chlorambucil, fludarabine, or rituximab; chlorambucil may produce the best results.³⁸ Rituximab, an anti-CD20 antibody, is particularly effective and well tolerated and may represent an alternative to chemotherapy, especially in the case of t(11;18) translocation.³⁹ Current data favor systemic treatments in MALT lymphomas, considering that these tumors may represent the early-stage manifestation of a systemic disorder of mucosal immunity.²⁶ Furthermore, the fact that surgical resection has not been shown to improve prognosis in some series is an additional argument against local treatments. Recently, the addition of rituximab to chlorambucil demonstrated a significant effect on survival in patients with MALT lymphoma.^{39a} Prognosis of MALT lymphomas is excellent, with an indolent and localized prolonged course. Historical series reported 5-year survival rates higher than 80%, and the more recent availability of rituximab may even improve these results.^{23-25,27} Local and systemic recurrences develop in about 50% of cases, but are usually controllable with chemotherapy. Evolution to high-grade B-cell lymphoma is seen in less than 5% of cases. Young age is the most significant favorable prognostic factor.

LYMPHOMATOID GRANULOMATOSIS

Lymphomatoid granulomatosis (LG), also called “angiocentric lymphoma,” is a malignant B-cell angiocentric and angiodestructive lymphoproliferative disorder. For a long time, LG was considered an inflammatory granulomatous disease owing to a clinical presentation similar to other granulomatoses, such as granulomatosis with polyangiitis (formerly Wegener disease) and eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome). Now, LG is recognized as a true EBV-related lymphoid malignancy. Differential diagnosis also includes allergic bronchopulmonary aspergillosis. The lung is the most frequent location, but the disease may also involve the brain, the skin, and the liver.⁴⁰⁻⁴³

LG forms multiple and confluent nodules composed of an atypical, angiocentric, and polymorphous lymphoid infiltration involving the vascular walls, from the subendothelium to the adventitial zones, with focal lumen obliteration. By immunohistochemistry, these lymphoid cells are characterized mostly as CD4⁺ T-lymphocytes, with scattered atypical cells of B phenotype.⁴⁰ Large B cells are infected with EBV in 65% of cases, a fact that correlates with the grade of the lesion. Pulmonary biopsy is required in most cases to exclude other granulomatoses.

LG arises in middle-aged patients between 40 and 50 years old, with a male predominance.^{41,42} Nearly all patients present with respiratory and systemic symptoms, consisting of cough, dyspnea, hemoptysis, chest pain, fever, and weight loss. Peripheral and mediastinal lymphadenopathy is absent. Prolonged immunosuppression is a frequent underlying condition. Hypereosinophilia may be observed in the blood and/or in the bronchoalveolar lavage. The typical radiologic presentation consists of multiple smooth bilateral nodules ranging from 2 to 10 cm mainly localized in the lower lobes, exhibiting a peribronchovascular pattern and mimicking multiple metastases (eFigs. 54-3 and 54-4).^{1,5,22,41} As in other granulomatoses, convergent nodules may migrate and form cavitated pseudotumoral masses. Ground-glass opacities may be present. Peripheral and mediastinal lymphadenopathy is absent. Lung biopsy is required in most cases to make the diagnosis.

Chemotherapy based on high-dose steroids with cyclophosphamide is the most frequently reported treatment. The additional use of rituximab may increase the efficacy of these cytotoxic agents.^{44,45} The overall prognosis is grim, with a 5-year survival of 30% to 40%, owing to progression to nodal diffuse aggressive lymphoma in 20% to 50% of patients. As in lymphoma, the main prognostic factors are age, extension of the lesions, and response to first-line chemotherapy.^{43,45} LG is increasingly considered a low-grade or early-stage lymphoma, and a histopathologic grading system has been developed, based on the degree of cellular atypia and necrosis, to predict the risk of evolution to high-grade lymphoma and to select patients for early aggressive treatment.⁴⁵

OTHER LYMPHOMAS AND LYMPHOPROLIFERATIVE DISEASES

Other primary pulmonary malignant lymphoproliferative diseases are very rare and include high-grade diffuse large B-cell lymphoma, intravascular large cell lymphoma, Hodgkin lymphoma, and plasmacytoma.

Primary pulmonary diffuse large B-cell lymphoma is likely underrecognized owing to its rapid spread to mediastinal nodes and other extrathoracic sites, which may hide its pulmonary origin.^{33,34} Histologically, it shows characteristics similar to those of diffuse large B-cell lymphomas at other sites, with diffuse infiltration of large blastic lymphoid cells, expressing pan-B antigens (CD20 and CD79a). Primary pulmonary high-grade B-cell lymphomas typically develop in immunocompetent patients in their sixth to seventh decade. In younger patients, large B-cell lymphoma may be caused by latent EBV infection, which may develop following drug-induced immunosuppression, as from methotrexate or antilymphocyte antibodies in

transplant recipients,^{46,47} or following HIV-related immunosuppression. In patients with HIV infection, the availability of highly active antiretroviral therapy led to the near disappearance of primary pulmonary high-grade lymphomas, which are now less frequent than MALT lymphomas in these patients.^{22,33} Patients often present with marked respiratory and systemic symptoms. Radiologic studies usually show multiple well-defined rounded solid masses of various sizes, more frequently in the subpleural areas of the lower lobes (see eFigs. 90-33 through 90-35).^{34,47} Chemotherapy is based on the same multiagent regimens as those used in high-grade nodal lymphomas, including doxorubicin (Adriamycin), prednisone, and rituximab.^{22,33} The overall prognosis is much worse than for MALT lymphoma, with a 5-year survival lower than 20%.

Intravascular large cell lymphoma is a variant of non-Hodgkin lymphoma, in which neoplastic lymphoid cells proliferate within the lumen of small and intermediate-sized blood vessels, resulting in thrombotic and ischemic complications.⁴⁶ Clinical manifestations are multiple, but lymphadenopathy is usually absent. Pulmonary imaging features include bilateral ground-glass opacities and/or sometimes migratory atelectatic shadows (eFig. 54-5).⁴⁸ Treatment with conventional combination chemotherapy with or without rituximab leads to remission and prolonged survival.^{22,48}

Primary pulmonary Hodgkin lymphoma has been reported exclusively in old studies, and might actually correspond to nodal Hodgkin disease with secondary pulmonary involvement.⁴⁹ On chest radiography, it is described as a solitary mass (eFig. 54-6) with cystic and heterogeneous features, typically involving the upper lobes, or as a multinodular disease. Diagnosis is based on the recognition of characteristic Reed-Sternberg cells at pathologic examination. The overall outcome is poorer than in nodal Hodgkin lymphoma.

Primary pulmonary plasmacytoma is a solitary lesion exclusively composed of atypical monoclonal plasmocytes, possibly associated with amyloid deposition, without evidence of extrapulmonary myelomatous disease.^{50,51} Again, the apparent decrease of the incidence of primary pulmonary plasmacytoma may be related to the increased sensitivity of biologic and imaging studies for the detection of primary extrapulmonary disease. Moreover, about one third of patients operated on for pulmonary plasmacytoma were reported to present with multiple myeloma in following years.^{50,51} Surgical resection is, however, recommended for solitary tumors, with a 5-year survival of 60%.⁵¹

CARCINOIDS AND OTHER NEUROENDOCRINE TUMORS

Primary lung neuroendocrine tumors share common histopathologic features and correspond to four different clinical and prognostic entities: (1) low-grade typical carcinoids, (2) intermediate-grade atypical carcinoids, and (3) high-grade large and (4) small cell neuroendocrine carcinomas.⁵² The small cell lung carcinomas are common, accounting for 15% to 20% of all primary lung malignancies. On the contrary, carcinoids and large cell neuroendocrine carcino-

mas account for 0.5% to 2% of lung tumors and are thus considered the most frequent lesions among the rare lung tumors.

PATHOLOGIC CLASSIFICATION

Neuroendocrine tumors share varying degrees of neuroendocrine morphologic features, including organoid nesting, the palisading and trabecular pattern, and “rosette-like” structures. Classification is mainly based on the mitotic index and the amount of necrosis.^{16,52} Typical carcinoids exhibit neuroendocrine features, with a mitotic index less than 2 mitoses per 10 high-power fields (2 mm²), and the absence of necrosis in a tumor that is more than 5 mm in diameter. Atypical carcinoids exhibit a mitotic index ranging from 2 to 10, or areas of focal necrosis. Peripheral carcinoids often may also be associated with small (<5 mm) neuroendocrine “tumorlets” and/or with diffuse hyperplasia of pulmonary neuroendocrine cells.⁵³ These lesions may correspond to early-stage in situ carcinoid proliferation.

Large cell neuroendocrine carcinomas exhibit a mitotic index higher than 10 (ranging from 70 to 80 in most cases) and extensive necrosis. Unlike small cell carcinoma, large cell carcinomas have large tumor cells, with moderate to abundant cytoplasm and, frequently, prominent nucleoli.^{16,52} Immunohistochemically, the expression of at least one neuroendocrine marker, including chromogranin, synaptophysin, or N-CAM (CD56), confirms the diagnosis. The pathologic classification also distinguishes large cell neuroendocrine carcinoma from *non-small cell lung cancer* (NSCLC) “with neuroendocrine differentiation,” a pattern without specific prognostic or therapeutic implications.⁵⁴

CARCINOID TUMORS

Excluding small cell lung cancer, more than 80% of lung neuroendocrine tumors are carcinoids.¹⁴ Carcinoids arise mostly in never-smokers (60% to 80% of cases).⁸ Carcinoids develop in the proximal airways in 60% to 70% of cases and may produce chronic cough, hemoptysis, and signs of bronchial obstruction. Peripheral carcinoids are asymptomatic, unless they are associated with diffuse hyperplasia of pulmonary neuroendocrine cells that produces bronchiolar obstruction in 50% of cases⁵⁵ and possible airflow obstruction. Unlike carcinoids in extrathoracic locations, lung carcinoids are small size lesions only rarely associated with liver metastases and do not generally produce the carcinoid syndrome (<2% of cases).^{5,11} CT shows a peripheral or proximal circumscribed solitary nodular lesion in 90% of cases,⁵⁵ often manifesting as a hilar or perihilar mass (eFig. 54-7). Carcinoid tumors may present as “iceberg-like” lesions, with a small amount of endobronchial growth and a prominent parenchymal mass (Fig. 54-2). In some cases, carcinoid tumors may present as endobronchial lesions, with or without (eFig. 54-8) lobar or segmental atelectasis. Calcification (see eFig. 54-7C) may be observed in up to 30% of cases.⁵⁵ Their hypervascularity (see eFig. 54-7B and C) can distinguish carcinoids from mucous plugging. Regional lymph node invasion is more frequent in atypical carcinoids (40% to 50% of cases vs. 10% to 15% of typical carcinoids) (eFig. 54-9), and the tumor-node-metastasis classification, although designed for

Figure 54-2 “Typical” carcinoid tumor: “iceberg-like” endobronchial mass. **A** and **B**, Axial chest CT displayed in lung windows in a 32-year-old woman with recurrent pneumonia shows complete obstruction of the left lower lobe bronchus (**B**, arrow), with a small portion of tumor protruding into the left mainstem bronchus (**A**, arrowhead), in a manner analogous to the small portion of an iceberg that protrudes above the ocean water. Left lower lobe postobstructive air trapping (**B**, arrowhead) is present, which confirms an airway origin for the lesion. **C**, Bronchoscopic image shows the left lower lobe lesion protruding into the left mainstem bronchus. (Courtesy Michael Gotway, MD.)

carcinomas, has been used to stage carcinoids.^{8,55} Although hypervascularized, carcinoids generally exhibit a low to moderate activity on PET scanning.⁵⁶ Imaging for somatostatin receptors using¹¹¹ Indium-labeled octreotide (eFig. 54-10) has shown great promise and may increase the sensitivity for diagnosis, staging, and follow-up for recurrence.⁵⁷ The risk of hemorrhage following endobronchial biopsy is less than 1%.⁵⁵

Surgery is the standard treatment for stage I-II and most stage III carcinoids, which account for 75% and 15% of cases, respectively. Typical carcinoids, with a low local recurrence rate, can be treated with limited resection with segmentectomy and regional lymph node dissection; this local approach is associated with local control and survival rates identical to that following extensive procedures.^{13,20} Endobronchial techniques, such as cryotherapy, have also been reported as an alternative approach for typical carcinoid but fail to ensure accurate counting of the mitotic index and, therefore, the confirmation of the subtype.⁵⁸ Atypical carcinoids, which have a higher local recurrence rate, require lobectomy and mediastinal lymph node dissection.^{13,20,59} Lung carcinoids metastasize in less than 10% of cases. In those cases, cisplatin-based chemotherapy is ineffective, whereas local treatment of metastases may lead to prolonged remission. Combination of everolimus plus octreotide may represent the best option.¹⁷ In sum, the most significant prognostic factor is the histopathologic subtype, because 5-year survival rates of typical and atypical carcinoids are 87% to 98% and 56% to 73%, respectively.¹²⁻¹⁶

LARGE CELL NEUROENDOCRINE CARCINOMA

The incidence of large cell neuroendocrine carcinoma has long been underestimated, probably because these tumors are often misdiagnosed as large cell undifferentiated carcinoma either on cytology or on tissue sections in the absence of immunostaining for neuroendocrine markers.^{16,60} Large cell neuroendocrine carcinomas are strongly associated with tobacco smoking (90% of cases).^{60,61} Clinical and radiologic (eFig. 54-11) features are similar to those of other bronchogenic carcinomas and, in most reported

series, treatment follows recommendations for NSCLC, including resection in stage I-II tumors.^{19,62} Epidermal growth factor receptor (EGFR) mutations may be present.⁶³ Efficacy of chemotherapy is significantly better, with up to 75% of response to the cisplatin-etoposide combination in a neoadjuvant (presurgical) setting.^{18,19,64,65} Several studies, including one prospective trial, showed a reduced metastatic recurrence rate and increased survival in patients receiving adjuvant chemotherapy even in early-stage tumors.^{60,62,64} Overall survival is better than in small cell carcinoma, with stage being the most significant prognostic factor. Five-year survival is 52% to 88%, 20% to 45%, and 0% to 15% in stages I-II, III, and IV, respectively.⁶⁰⁻⁶⁴

RARE MALIGNANT PRIMARY PULMONARY EPITHELIAL TUMORS

MUCOEPIDERMOID CARCINOMA

Mucoepidermoid carcinoma is the most frequent salivary gland-type tumor arising in the lung; other subtypes include adenoid cystic carcinoma and epithelial-myoeplithelial carcinoma. Mucoepidermoid carcinoma is a mixed malignant tumor characterized by the presence of squamous cells, goblet mucin-secreting cells, and cells of intermediate type (Fig. 54-3C and D).⁶⁵ Identification of these three cellular subtypes in cytologic examination is pathognomonic.^{65,66} Tumors are classified as low-, intermediate-, and high-grade lesions, depending on the mitotic index, the degree of cellular atypia, and the degree of necrosis. High-grade tumors contain predominantly squamous and intermediate cells and tend to infiltrate the lung parenchyma.

Mucoepidermoid carcinoma in adults mostly develops between the third and fourth decades, with an equal sex distribution.⁶⁶⁻⁶⁹ High-grade tumors (30% of cases) are usually diagnosed in older patients. Mucoepidermoid carcinoma is often associated with tobacco smoking. Symptoms, including dyspnea, cough, and hemoptysis, are related to the level of bronchial obstruction (eFig. 54-12). Metastases

Figure 54-3 Primary pulmonary mucoepidermoid carcinoma. **A**, The tumor is located in the right upper lobe and is invading the mediastinum (arrow). Radiologic imaging features are identical to those of non-small cell lung cancer. **B**, A metastatic mass is discovered on clinical examination of the abdomen. Axial enhanced abdominal CT confirms the location in the anterior abdominal wall (arrow). Histopathologic features: a mixture of squamoid (**C**) and mucin-secreting (**D**) cells (arrows). (**C** and **D**, Original magnification $\times 40$.)

are found at time of diagnosis in 20% of cases, mainly in the liver, the bone, and the subcutaneous tissues (see Fig. 54-3B). In the lung, mucoepidermoid carcinoma often presents as a well-circumscribed homogeneous, lobulated homogenous mass, often with cystic features and/or calcification (see Fig. 54-3A).⁷⁰ The lesion is solitary in 40% to 70% of cases. Hilar involvement is found only for high-grade lesions. There is increased uptake on PET scanning.^{70,71} Proximal mucoepidermoid tumors can be diagnosed using endobronchial biopsy.⁶⁷

Treatment is the same as for NSCLC with, when feasible, extensive surgical resection including mediastinal lymph node dissection.⁶⁶⁻⁶⁹ High-grade lesions have often been reported to receive postoperative radiotherapy and chemotherapy, without clear benefit. Chemotherapy of metastatic tumors in most cases is based on cisplatin and/or 5-fluorouracil. As in NSCLC, a small number of patients with mucoepidermoid carcinoma may benefit from EGFR tyrosine kinase inhibitors.⁷² Prognosis is correlated with the grade of the lesion, the existence of nodal involvement, and the success of the initial surgical resection. Low-grade mucoepidermoid tumors mostly present in children and young adults, usually without hilar involvement, and have a 5-year survival ranging from 70% to 80%. High-grade tumors have a substantially worse prognosis, with a 5-year survival of only 30% to 45%.

PNEUMOBLASTOMA

Pulmonary blastoma is a biphasic tumor that is classified among the sarcomatoid carcinomas in the current World Health Organization classification. This tumor contains both an epithelial well-differentiated component, showing tubular architecture resembling the normal fetal lung, and

a mesenchymal undifferentiated stroma, defining the “blastema-like” configuration.⁷³ Pulmonary pneumoblastoma arises in adults and must be distinguished from “pleuropulmonary blastoma,” a tumor of early childhood related to other embryonic neoplasms, such as nephroblastoma and neuroblastoma.

Pulmonary pneumoblastoma arises in patients aged 30 to 45 years, with a marked female predominance (70% of cases) and frequent association with tobacco smoking.⁷⁴⁻⁷⁶ CT shows a solitary circumscribed homogeneous mass,⁷⁷ often with cystic and necrotic features. PET scans show increased uptake. In many cases, the tumor is initially thought to be a bronchogenic carcinoma, and complete surgical resection with mediastinal lymph node dissection ensures both the initial diagnosis and the therapy.^{74,76,78,79} Adjuvant treatment, mostly consisting of radiotherapy, has been reported in a few cases following incomplete resection or in patients with N2 mediastinal involvement.^{76,79-82} In unresectable tumors, chemotherapy is based on protocols used for sarcomas, including doxorubicin and ifosfamide. In most recent reports, survival is better than in NSCLC, especially in completely resected cases.⁷⁴

SARCOMATOID CARCINOMAS (OTHER THAN PNEUMOBLASTOMA)

Sarcomatoid carcinomas are a group of poorly differentiated non-small cell carcinomas that contain a sarcomatous component. In addition to pneumoblastoma, four subtypes are recognized:

1. Pleomorphic carcinoma, which corresponds the combination of adenocarcinoma, squamous cell carcinoma, or large cell carcinoma with spindle or giant cells.^{83,84}

2. Spindle cell carcinoma, which consists exclusively of fascicular cells.
3. Giant cell carcinoma, composed of highly pleomorphic mononucleated or multinucleated cells.⁸⁴
4. Carcinosarcoma, containing a mixture of carcinoma (frequently of epidermoid subtype) and poorly differentiated fibromatous sarcoma.⁸⁵

Sarcomatoid carcinoma has been defined in the 1999 World Health Organization classification. These tumors represent from 0.3% to 1.3% of lung tumors, and their specific clinical and radiologic features are rarely reported. Moreover, small biopsies usually do not disclose both the epithelial and the sarcomatous components of the tumor, which is then misdiagnosed as NSCLC in more than 60% of cases.¹ Clinical features are similar to other non-small cell carcinomas. Sarcomatoid carcinomas develop mostly in men, at a mean age of 65 years at diagnosis.⁸³⁻⁸⁶ Tobacco smoking is described in more than 80% of cases. Radiologic studies usually show a solitary voluminous peripheral heterogeneous mass invading the chest wall in 60% of cases.^{87,88} Vascular invasion is observed in 20% of cases. PET scans show increased uptake.

Sarcomatoid carcinomas are often treated as other non-small cell carcinomas. Alternatively, chemotherapy has been reported to follow soft tissue sarcoma regimens.⁸⁹ Response to EGFR-targeted therapies is infrequent, which may be related to frequent *KRAS* mutations in the epithelial component.^{90,91}

Contrary to pneumoblastomas, the other sarcomatoid carcinomas have been considered as highly aggressive tumors with early metastatic spread,⁹² especially in unusual sites such as the esophagus, the peritoneum, the kidney, and the subcutaneous tissues. Chemoresistance is frequent.⁹³ Median overall survival ranges from 6 to 20 months.^{83-86,88} The main favorable prognostic factors include tumor size, stage, and the absence of mediastinal involvement.^{83-86,88-90,94}

PRIMARY PULMONARY SARCOMAS

Primary pulmonary sarcomas account for 20% of all primary rare lung malignancies and comprise (1) parenchymal lung sarcomas, which usually present as a lung mass, and (2) pulmonary vascular sarcomas, which include pulmonary artery sarcomas, which may mimic chronic pulmonary embolism, and small vessel sarcomas, which may produce interstitial lung disease.^{1,2}

PARENCHYMAL SARCOMAS

Primary lung parenchymal sarcomas show identical pathologic subtypes to those of their soft tissue counterparts, with a wide spectrum of differentiation from low to high grade. Leiomyosarcoma is the most frequent primary lung sarcoma⁹⁵⁻⁹⁸ and presents with fascicles of spindle cells at right angles and/or an epithelioid growth pattern with marked hypercellularity and polymorphism. Tumor cells have irregular nuclear chromatin and prominent nucleoli.

Immunohistochemistry shows a high level of muscular actin, vimentin, and h-caldesmon, an actin-binding protein. Synovial sarcoma is the second most frequent subtype and presents with a prevalent monophasic growth pattern consisting of interweaving fascicles of densely packed spindle cells. As in their soft tissue location, the chromosomal translocation t(X;18) (p11.2;q11.2) is pathognomonic of the diagnosis⁹⁹ and results in the fusion of two genes, *SYT-SSX1* and *SYT-SSX2*. Other subtypes include pleomorphic sarcoma, made of atypical spindle cells showing a “cartwheel” or so-called storiform or radiating pattern, with elongated nuclei and giant cells with multiple and bizarre nuclei and prominent nucleoli, as well as osteosarcoma and chondrosarcoma. Because most mesenchymal malignant tumors have a benign counterpart, pathologic examination must first evaluate the grade of the lesion, according to the three-grade system of the French Federation of Cancer Centers Sarcoma Group,¹⁰⁰ and second rule out other epithelial tumors with sarcomatoid differentiation, such as pneumoblastoma or myofibroblastic tumors.^{1,5} Differential diagnosis also includes “benign” metastases from uterus (metastasizing leiomyoma) or bone (giant cell tumor).

Compared with their soft tissue counterparts, primary pulmonary sarcomas present in older patients, mainly in the sixth to eighth decade.^{96-98,101-104} Clinical symptoms are nonspecific and usually consist of cough, dyspnea, and hemoptysis, depending on the size and the location of the lesions. The incidence of radiation-induced sarcomas has decreased because cobalt-based radiotherapy has been abandoned.¹⁰⁵ Unlike metastatic sarcoma, primary pulmonary sarcoma presents as a solitary lesion (eFigs. 54-13 and 54-14), with heterogeneous cystic, necrotic, or hemorrhagic features but well-defined circumference. Size ranges from 4 to 25 cm (Fig. 54-4A). PET scanning shows increased uptake (see Fig. 54-4B and eFig. 54-14D).¹⁰⁶ Tumor progression is mainly local, and mediastinal lymph node invasion and systemic metastases are rare at the time of diagnosis (<2%).^{95,96,101}

Surgery is then the most effective initial treatment, and complete resection is obtained in 80% of cases.^{95-98,101-104} Strategies developed in soft tissue sarcoma may not be applicable to primary lung sarcomas: for example, neoadjuvant chemotherapy, based on anthracycline and ifosfamide, is commonly used in soft tissue locations but has been disappointing in primary lung tumors.^{96,98,107,108} In case of unresectable lesions, chemoradiation may be the best therapeutic strategy. As in soft tissue sarcoma, the chemotherapeutic drug trabectedin may be an option for second-line treatment. Prognosis mainly depends on the completeness of initial surgical resection, which, when combined with the grade of the lesion, is the best predictive factor of recurrence-free and overall survival. Overall 5-year survival varies from 30% to 50%^{95-98,101-104} and may be better for leiomyosarcomas.¹⁰⁹

VASCULAR SARCOMAS

Primary pulmonary vascular sarcomas include pulmonary artery sarcomas and small vessel sarcomas, corresponding to epithelioid hemangioendothelioma and its high-grade counterpart, angiosarcoma.¹¹⁰

Figure 54-4 Primary pulmonary leiomyosarcoma. **A**, Chest radiograph shows a large circumscribed homogeneous mass in the left lung (arrow). **B**, Coronal PET shows marked hypermetabolism within the lesion (arrow).

Pulmonary artery sarcoma presents as an endoluminal polypoid or nodular mass, which spreads along the intima of the pulmonary artery. Histologic features consist of an undifferentiated spindle cell proliferation, with marked cellular pleomorphism and high mitotic index.¹¹⁰ Leiomyosarcoma is the most frequent subtype (60% of cases).^{110,111} Pulmonary artery sarcomas mainly develop in patients in their fifth to sixth decade.^{112,113} Symptoms may mimic pulmonary embolism, with dyspnea, chest pain, cough, and hemoptysis.¹¹²⁻¹¹⁴ Failure of anticoagulants in this setting, as well as the presence of symptoms of weight loss and fever (arising in 40% of cases), may also suggest the diagnosis. Imaging findings also help differentiate between pulmonary artery sarcoma and pulmonary embolism: CT scanning may show a polypoid filling defect in the pulmonary artery but, contrary to thromboembolic disease, sarcoma forms a contiguously soft, smooth, tapering tissue, with possible extravascular nodular spread in the parenchyma (40% of cases) (eFig. 54-15 and Video 54-1) and localized ground-glass opacities (Fig. 54-5A and B).^{113,114} Sarcoma also presents with a heterogeneous appearance including areas of necrosis and hemorrhage, and with intense hyperactivity on PET scanning (see eFig. 54-15F and G).¹¹⁵ Magnetic resonance imaging (MRI) shows intermediate to mildly increased signal on T1-weighted images, often with heterogeneous enhancement (eFig. 54-16), and T2-weighted images show intermediate to diminished signal relative to skeletal muscle; furthermore, the intravascular mass may enhance, a feature not typically encountered with uncomplicated thromboembolic disease. Surgery is the only potentially curative treatment and, even if performed in an emergency setting in case of acute right-sided heart failure, allows resectability in 60% to 75% of cases¹¹¹⁻¹¹⁶ (see Fig. 54-5C). Alternatively, heart and lung transplantation may be an alternative option for unresectable tumors. A slight improvement of overall survival has also been reported following adjuvant chemotherapy and/or radiotherapy. Contrary to soft tissue sarcoma, prognosis is mainly related to tumor location, because half of the patients die as a result of the progressive obstruction of the pulmonary trunk.¹¹⁵ Reoperation is feasible in 30% of cases. However, in recent series, overall median survival is as low as 6 to 12 months (eFig. 54-17).^{114,115}

Epithelioid hemangioendothelioma (EHE), a small vessel sarcoma, is a low- to intermediate-grade mixed epithelioid, endothelial, and vascular tumor.^{117,118} Lung is the most frequent extrahepatic location (10% of cases), because EHE can also arise from the liver (63% of cases), the bone (8% of cases), and the skin (6% of cases).^{119,120} EHE was initially considered an intravascular and intra-alveolar extension of bronchoalveolar carcinoma and thus was called “intravascular bronchoalveolar tumor.”¹¹⁷ Now, however, it is clearly identified as a mesenchymal tumor corresponding to low-grade angiosarcoma. EHE is characterized by polypoid nodules, with a central sclerotic paucicellular zone, growing into the alveolar spaces with an angiocentric distribution. Lymphangitic spread may mimic metastatic carcinoma. A recently identified translocation t(1;3) (p36.3;q25) involving the *PAX7* gene, which encodes a transcription factor involved in regulation of development, may be helpful in making the diagnosis.¹²¹ EBV RNA sequences are detected in 90% of cases. Overlapping entities with IgG4-related disease have been described (see later).

Clinically, 80% of cases of EHE are seen in white females.^{119,120,122} The tumor is asymptomatic in 50% of cases; when present, symptoms are nonspecific and include pleuritic chest pain, nonproductive cough, dyspnea, and rarely hemoptysis. Physical examination may reveal inspiratory crackles in 30% of cases. By CT imaging, EHE appears either with bilateral slow-growing perivascular multiple nodules, usually located adjacent to small vessels or bronchi, or with predominant infiltrative ground-glass opacities (eFig. 54-18) with a micronodular pattern, mimicking carcinomatous lymphangitis. EHE nodules usually range from 3 to 50 mm, and their number varies from 10 to 20 lesions.^{119,120,122} Nodules in patients with EHE may show increased uptake on PET scans.¹²³

Although there are a few reports of spontaneous remission, the complete resection of all pulmonary nodules is the only curative treatment of EHE.^{124,125} Surgery remains effective even in cases of localized recurrence. In contrast, EHE is generally insensitive to chemotherapy (cisplatin-based) or radiotherapy. Treatments with rituximab or antiangiogenic kinase inhibitors, such as sorafenib or bevacizumab, have been reported to be effective in isolated case reports.¹²⁶ In most cases, EHE is a slow-growing tumor

Figure 54-5 Pulmonary artery sarcoma. **A**, CT displayed in soft tissue windows shows a mass filling the pulmonary artery lumen (arrows). **B**, CT displayed in lung windows shows peripheral, irregular alveolar opacities (arrows) without pleural contact. **C**, Specimen at pneumonectomy shows the infiltration of the pulmonary artery wall by the tumor (arrow).

that rarely metastasizes and is associated with a median survival of 5 to 6 years. Endobronchial spread, pleural effusion, and extended endovascular disease have been identified as unfavorable prognostic factors.¹²⁴

Angiosarcoma is a high-grade primary pulmonary vascular sarcoma considered a counterpart of EHE. However, no direct transformation from EHE to angiosarcoma has been reported yet. Clinical features of angiosarcoma are similar to EHE, but massive hemoptysis is more frequent. Radio-

logic features of angiosarcoma include multiple nodules with a typical surrounding halo of ground-glass attenuation, with a specific “cauliflower-like” appearance on T2-weighted MRI.¹²⁷ This aspect may be shared by other disorders, including malignancies (e.g., adenocarcinoma with lepidic pattern, metastatic sarcomas, choriocarcinoma, melanoma, lymphoma), infectious diseases (e.g., mycobacteriosis, aspergillosis, cytomegalovirus infection), granulomatosis with polyangiitis, and eosinophilic conditions. Management of angiosarcoma is not established: surgical resection is rarely possible owing to local and regional invasion; radiotherapy and chemotherapy are poorly effective as seen in other locations of angiosarcoma.

INTRATHORACIC PSEUDOTUMORS

Pseudotumors represent a wide range of etiologic, pathologic, and clinical-radiologic disorders that all share some degree of reactive inflammation and may present with some cancer-related biologic hallmarks. Pseudotumors may mimic the clinical and radiologic features of various intrathoracic diseases.

INFLAMMATORY MYOFIBROBLASTIC TUMOR

Inflammatory myofibroblastic tumor (IMT) is the most representative entity of the pulmonary pseudotumors^{6,7,128} and encompasses a wide spectrum of lesions previously called “inflammatory pseudotumor,” “fibroma,” “fibroxanthoma,” “fibrous histiocytoma,” “plasma cell/mast-cell/solitary granuloma,” “plasma cell histiocytoma complex,” or “pseudosarcomatous tumor.” IMT has a prevalence of 0.04% of resected pulmonary neoplasms in the surgical series of the Mayo Clinic.⁶ IMT, which includes both benign and malignant features, represents an archetype of borderline neoplastic/non-neoplastic disorders.⁵

IMT appears as an intraparenchymatous well-circumscribed mass of variable size.¹²⁸⁻¹³⁰ Histologically, the tumor is made of irregular proliferation of fibroblasts and myofibroblasts intermixed with an infiltrate of inflammatory cells, mainly lymphocytes and plasma cells. Three distinct histologic patterns are usually recognized^{6,7,128-130}:

1. Plasma cell variant, also called the “lymphoplasma-cytic” variant, which is composed of inflammatory myxoid proliferation with fascicles of spindled fibroblasts or myofibroblasts, abundant lymphocytes and plasma cells, and minimal fibrous connective tissue.
2. Fibrohistiocytic type, which appears as a compact spindle-cell pattern simulating fibrous histiocytoma that is characterized by a myxoid proliferation of fibroblasts and myofibroblasts associated with polyclonal plasma cells, xanthoma cells, and rare giant cells.
3. Organizing pneumonia-like type, which has a hypocellular pattern characterized by dense collagen with sparse spindle cells.

The proliferating myofibroblastic cells show no cellular atypia, no necrosis, and only rare mitotic figures. The myofibroblastic cells usually stain for vimentin and smooth

muscle actin. Differential pathologic diagnosis includes all the diseases composed of fibroblasts and myofibroblasts, some of which may overlap with IMT: benign and malignant fibrous histiocytoma, myofibroblastoma, inflammatory fibrosarcoma, spindle cell carcinomas, plasmacytoma, and organizing pneumonia.

The concept of IMT as a proliferating neoplasm has been questioned.⁷ Historically, IMT, which was then called “inflammatory pseudotumor,” was thought to originate from organizing pneumonia through an exaggerated inflammatory response to injury. Older case reports emphasized that, in as many as 30% of cases, chronic or repeated infections could be a potential cause, but this concept was reconsidered with more recent reports that included chest CT studies, suggesting that recurrent pulmonary infections were rather a consequence of bronchial obstruction by the tumor.^{6,129} The concept of IMT as an immunologic disorder was raised after the detection of EBV and human herpesvirus 8 sequences in myofibroblastic cells, with associated expression of cytokines such as interleukin-6 and -8, and cyclin D1.^{6,131} The recent identification of IgG4 expression in polyclonal plasma cells extracted from intrathoracic IMTs suggested that an immunopathologic process may participate in the development of these tumors, especially the plasma cell variants. Such proliferation of IgG4-positive cells has also been associated with autoimmune disorders, including sclerosing pancreatitis and retroperitoneal and mediastinal fibrosis.¹³² IMTs may then be part of IgG4-related disease, a newly recognized fibroinflammatory condition characterized by tumefactive lesions, a dense lymphoplasmacytic infiltrate rich in IgG4-positive plasma cells, storiform fibrosis, and often, but not always, elevated serum IgG4 concentrations. Based on molecular data, myofibroblasts are considered to be pivotal in the development of IMT. Clonal gene rearrangements may be observed,¹³³ especially involving the *anaplastic lymphoma kinase* (*ALK*) gene located in region 2p23.¹³⁴ *ALK* overexpression is observed in 40% to 70% of IMTs at immunohistochemistry, but may also be at low levels in a wide variety of non-IMT soft tissue tumors. *ALK* rearrangement is identified in 40% to 50% of IMT cases, especially in younger patients, and most frequently consists of t(1;2)(q21;p23) translocation implicating the tropomyosin 3 gene.¹³⁵ Other translocations have been reported.¹³⁶ Given the oncogenic nature of *ALK* activation, these data lead some authors to consider IMT as a true neoplasm. Other elements further reinforce this concept, including the presence of vascular invasion, the local recurrence rate as high as 25%,⁶ the existence of multifocal lesions in 5% of cases, reports about malignant transformation, and genomic and expression profiling data, showing DNA aneuploidy, abnormal p53 expression, and up-regulation of other known cancer-related genes such as glutathione-S-transferase.¹³⁷ Overlap exists between IMT, IgG4-related disorders, and inflammatory fibrosarcoma that exhibits prominent cellular atypias and necrosis.

Pulmonary IMTs usually appear before the fourth decade, accounting for more than 50% of pulmonary tumors in children.^{6,129,138} Patients are asymptomatic in about 60% of cases, or may present with nonspecific symptoms, including chronic cough, dyspnea, or rarely hemoptysis. At imaging,

Figure 54-6 Inflammatory myofibroblastic tumor. CT performed for a 31-year-old man who presented with persistent cough and hemoptysis following infectious pneumonia. A poorly defined infiltrative-appearing opacity is present in the posterior and medial left lower lobe (arrow). Percutaneous transthoracic needle biopsy showed polymorphic inflammation without tumor cells.

IMT appears as a solitary well-circumscribed peripheral mass, ranging from 2 to 15 cm in size (Fig. 54-6; eFig. 54-19). Contrary to its presentation at extrathoracic locations, pulmonary IMT is usually solitary. Calcifications are observed in 15% of cases. The usual stability in size over time is an important imaging feature. Multifocal and bilateral IMTs are exceptional (eFig. 54-20) and are considered as overlapping forms of low-grade fibrosarcoma or malignant fibrous histiocytoma. IMTs are usually hypermetabolic on PET scanning. Extrapulmonary involvement is seen in 10% to 20% of cases and is mostly observed in the mediastinum and pleura. Conversely, extrapulmonary IMTs may metastasize to the lung, especially in younger patients. Preoperative diagnosis with endoscopic or percutaneous biopsies remains difficult due to the heterogeneous morphology of IMTs. Cytologic fine-needle aspiration accuracy was as low as 42% in a recent study.¹³⁹

Even if historically considered a benign lesion with possible spontaneous regression, IMT is usually treated by surgical resection due to its tendency to grow, to provoke local complications including hemoptysis and infection, and to relapse with local, pleural, parietal, or mediastinal invasiveness (15% to 25% of cases and 3% to 5% of cases, respectively).^{140,141} The need for adjuvant treatment in case of incomplete resection has not been evaluated. In nonoperable patients, focal conformation radiotherapy or corticosteroid challenge may represent an alternative. Corticosteroids are reported to induce objective responses in as many as 50% of cases, especially in predominantly plasma-cell tumors and IgG4-positive tumors.¹⁴¹ In recurrent or multifocal lesions, chemotherapy may use the same regimens as for soft tissue sarcomas. Crizotinib, a small pharmacological tyrosine kinase inhibitor of *ALK*, was recently reported to produce tumor responses in two patients with *ALK*-rearranged extrathoracic IMTs.¹⁴²

Patients with a resected IMT have a 5-year overall survival ranging from 75% to 100%.¹³⁹⁻¹⁴² Transformation to low- and/or high-grade fibrosarcoma has exceptionally been reported and may correspond to initially misdiagnosed

Figure 54-7 Mediastinal fibrosis. **A**, CT performed for a 32-year-old woman who presented with progressive dyspnea and superior vena cava syndrome. Poorly defined soft tissue opacities are seen throughout the mediastinum, compressing the right pulmonary artery (arrow). Surgical biopsy was performed to make the diagnosis. Coronal early arterial (**B**) and late arterial (**C**) magnetic resonance angiograms show severe stenosis of the superior vena cava (arrow), requiring intravascular stent placement (visible in **A**, arrowheads). Note the markedly impaired perfusion to the right lung compared with the left, implying the presence of severe right pulmonary arterial stenosis.

high-grade tumors.¹⁴¹ ALK-positive tumors are considered to be more aggressive but can recur locally regardless of ALK expression level.¹³⁴ The most consistent prognostic factor is the initial invasiveness of the tumor.

MEDIASTINAL FIBROSIS AND HYALINIZING GRANULOMA (see Chapter 84)

Similar to IMT, mediastinal fibrosis and hyalinizing granuloma both consist of tissue infiltration by dense collagen fibrosis forming lamellar bands, interspersed with lymphocytes and plasma cells.¹⁴³⁻¹⁴⁵ These two entities differ by the primary anatomic location: mediastinal fibrosis, also known as sclerosing mediastinitis, predominantly involves the mediastinum, with possible extension to the lung parenchyma; hyalinizing granuloma involves the lung parenchyma without contiguous involvement of the mediastinum. Overlap exists between these entities and other fibrosing disorders such as IMT, retroperitoneal fibrosis, and other IgG4-related disorders.

A hallmark of mediastinal fibrosis is the obstruction of major mediastinal veins with multifocal venous infarcts observed in the tumor leading to cellular fibrosis, hemorrhage, and necrosis. Mediastinal fibrosis has mostly been described in North America, where it is thought to result in most cases from exacerbated responses to *Histoplasma*.¹⁴⁶ Because the fungus is not typically cultured, it is thought that the fibrosis is a response to fungal antigens leaking from mediastinal nodes. Mediastinal fibrosis may be idiopathic, familial, or associated with various disorders, including infections with other fungi, such as *Aspergillus* or *Cryptococcus*, and tuberculosis or sarcoidosis. It has also been described following therapy with radiation, ergot derivatives, and beta-blockers. Autoimmune reactions may also participate, because an association with elevated serum IgG4 syndrome has been reported.¹⁴⁷ Clinically, mediastinal fibrosis is observed in the fourth decade, with a slight male predominance. Patients may be asymptomatic or develop chest pain, fever, hemoptysis, and dyspnea, as well as signs related to invasion of mediastinal structures. Pulmonary venous infarction can be the first manifestation of the disease. The severity of symptoms is related to the extension of the fibrosis. At imaging, mediastinal fibrosis

presents either as a localized mass (eFig. 54-21), possibly calcified, in the paratracheal, hilar, or subcarinal areas, or as diffuse infiltration throughout the mediastinum, without calcification (Fig. 54-7 and eFig. 54-22). The lung may be marginally affected, with consolidated areas resulting from venous infarction (see eFig. 54-22A and B), and possible pleural effusion. Surgical biopsy is often necessary to obtain a definite diagnosis. Prognosis depends on the structures involved. Treatment of mediastinal fibrosis may involve surgical resection, which often may be only palliative given the extent of the fibrosis, or the use of stents to restore patency of critical vessels. There is little evidence to support use of antifungal agents or corticosteroids, but trials of these are sometimes attempted.

Hyalinizing granuloma is seen in young to middle-aged adults with a slight predominance in men.¹⁴⁸ Patients usually have symptoms (80% of reported cases), consisting of cough, dyspnea, and pleuritic chest pain. Association with other fibrosing diseases has been reported, including mediastinal fibrosis (15% of cases) and retroperitoneal fibrosis (10% of cases). The radiologic presentation is that of solitary or multiple well-circumscribed lung nodules, usually 2-4 cm in size, which may grow over time and thus mimic cancer. The lesion may be found in the context of sarcoidosis and IgG4-related disease (Fig. 54-8).¹⁴⁹ The main differential diagnosis is nodular amyloidosis, because hyalinizing granuloma may demonstrate factitious Congo red positivity. The clinical course is benign.

OTHER PSEUDOTUMORS

The most common mechanism causing the development of a pseudotumor is thought to be an exaggerated host response to injury. Developmental pseudotumors include benign lesions such as hamartomas (eFigs. 54-23 through 54-27), leiomyomas, and choristomas.^{4,5,9} Tissue remnants or heterotopias related to embryologic variation is another etiologic group, the most frequent entity being minute meningioma-like nodules (eFig. 54-28) that correspond to glial heterotopias.¹⁵⁰ Similarly, clear cell tumors, also called “sugar tumors,” are derived from perivascular epithelioid cells of the lung epithelium; these cells are of neuroectodermal origin and are also implicated in the

Figure 54-8 Hyalinizing granuloma. **A**, Chest CT performed for a 62-year-old man with a history of sarcoidosis, COPD emphysema, and liver transplantation for cirrhosis shows right lower lobe parenchymal consolidation with surrounding interlobular septal thickening (arrow). **B**, Axial PET scan shows tracer activity within the mass (arrow). The patient presented with recurrent spontaneous pneumothorax and underwent thoracoscopy for pleurodesis. Resection of the lesion was performed, leading to the diagnosis of hyalinizing granuloma.

development of perivascular epithelioid cell tumor and lymphangioleiomyomatosis.

Functional pseudotumors are related to dysfunctional pathophysiologic states, often of an endocrine nature, and are rare in the lung parenchyma. Iatrogenic pseudotumors are due to several medical procedures that can produce tissue reactions, most of which are reparative in nature. Infectious pseudotumors may be produced by mycobacteria (tuberculoma), fungi (aspergilloma), or even viruses (EBV, HIV, cytomegalovirus). The pathogenesis of these tumors may be complex, possibly implicating multiple mechanisms. The clinical and radiologic features of these tumors may be similar to that of IMT.

BORDERLINE ENTITIES

Benign tumors and preneoplastic conditions of the lung are considered elsewhere in Chapter 56. *Borderline* neoplastic and non-neoplastic disorders include entities that are generally considered to have benign behavior despite being associated with true neoplasm or presenting with some pathologic or molecular characteristic of neoplasia, including clonal proliferation. Borderline lesions may also have features of malignant behavior, such as invasion and recurrence following resection. These disorders may also present as pulmonary nodules or infiltrative disease, mimicking bronchogenic carcinoma or interstitial pneumonias, respectively.

MESENCHYMAL BORDERLINE DISORDERS

Some benign lesions, presenting as slow-growing intraparenchymal masses with homogeneous attenuation and regular contours, may present with clonal chromosomal aberrations. For example, hamartomas may exhibit gene rearrangements in regions 12q15 and 6p21.¹⁵¹ These regions contain the *high mobility group AT-hook* genes, respectively, encoding nonhistone nuclear proteins that

participate in the regulation of gene expression via alteration of chromatin structure. Interestingly, similar alterations have been described in other mesenchymal tumors. Similarly, multiple minute pulmonary meningothelial-like nodules (see eFig. 54-28), which are millimeter-sized nodular proliferations of oval to spindle-shaped cells resembling meningioma and arranged in a nested pattern, exhibit loss of heterozygosity in multiple genomic loci in 33% of cases.¹⁵² Relationship of minute meningothelial-like nodules with primary pulmonary meningioma is not certain, given the contrast between the relatively high prevalence of meningothelial-like nodules and the low frequency of meningioma as a primary lung tumor.

RESPIRATORY TRACT PAPILLOMATOSIS

Some lesions thought to be benign may have a borderline presentation and outcome. One relevant example is recurrent respiratory papillomatosis. Papillomas usually present in the upper respiratory tract but may rarely spread to the lung parenchyma (less than 5% of cases).^{153,154} Histologically, squamous papillomas are usually exophytic with an epithelial layer covering a central fibrovascular core that forms a frondlike architecture protruding into the lumen of the airway. Squamous papillomas are lined by stratified squamous epithelium, sometimes keratinized. Distal papillomas exhibit a more inverted growth pattern. Papillomas may exhibit imaging features similar to those of lung cancer, including heterogeneous, cavitating, or poorly defined masses.

Pulmonary papillomas may be solitary or multiple (eFigs. 54-29, 54-30, and 54-31); if multiple, these are associated with multiple papillomas of the upper respiratory and aerodigestive tract. As in other locations, the pathogenesis of squamous papillomas is linked with *human papillomavirus* (HPV) infection, often acquired at birth.¹⁵⁵ Specifically, HPV type 11 infection has been reported to bear a high-risk of transformation of papilloma to squamous cell carcinoma (eFig. 54-32).¹⁵⁶ Molecularly, loss of the tumor suppressor genes *TP53*, *RB*, and *P21* has been reported in squamous

Figure 54-9 Pulmonary squamous cell carcinoma development in a patient with papillomatosis. **A**, Chest CT performed for a 32-year-old woman with a history of upper and lower respiratory tract papillomatosis, complaining of worsening cough and weight loss shows a subpleural mass in the right lower lobe (*arrow*). A thin-walled cyst is also present within the right lower lobe, and small centrilobular nodules are seen in the left lower lobe. Percutaneous transthoracic needle biopsy showed squamous cell carcinoma. **B**, PET shows increased uptake of the mass (*arrow*); moderate uptake of the mediastinal nodes was thought to be related to papillomatosis. Surgical resection was performed.

cell carcinomas originating from papillomas. Mutation of HPV-11 with duplication of promoter and oncogene regions has been described in a case responding to vorinostat.¹⁵⁷ PET scanning may not be useful given the mild hypermetabolism of high-grade papillomas. Pathologically, the distinction with invasive squamous cell carcinoma can be difficult in some exophytic cases or when there is atypical cytology. Given this uncertain malignant potential and the difficult differential diagnosis with lung cancer, complete resection of papillomas is recommended if possible; complete resection may not be possible in the setting of multiple and bilateral lesions (Fig. 54-9).

NODULAR LYMPHOID HYPERPLASIA

Pulmonary *nodular lymphoid hyperplasia* (NLH), historically called “pseudolymphoma,” is a nodular reactive polyclonal lymphoid proliferation infiltrating the lung, characterized by low-grade histology, presence of lymphoid follicles, and a benign clinical course.^{158,159} Histologically, NLH corresponds to lymphoid follicles with intercalated prominent plasma cells and usually mild interstitial fibrosis. Lymphocytes and plasma cells may distribute along lymphatics in the bronchovascular bundles and interlobular septa. Immunohistochemistry shows a mixture of polytypic B and T cells. No immunoglobulin heavy chain gene rearrangement has been identified. Differential diagnoses are MALT lymphoma, lymphocytic interstitial pneumonia, lymphomatoid granulomatosis; overlap entities, such as “atypical lymphoid proliferation,” have also been described. Sjögren syndrome may also have peribronchial lymphocytic infiltrates and may be associated with true lymphoma. In several cases of pulmonary NLH compared to other lymphoid proliferations of the lung, NLH was found to overexpress IgG4, suggesting that NLH may lie within the family of IgG4-related sclerosing diseases.¹⁵⁹

In a series of 14 well-characterized NLHs published in 2000,¹⁵⁸ most patients (81%) were asymptomatic. Radiologic presentation was that of a solitary peripheral nodule in nine patients, median size was 3 cm, and multifocal nodules were seen in five patients. Five patients (36%) also had concomitant hilar, mediastinal, or paraesophageal lymphadenopathy. In most cases, given the initial consideration of lung cancer, treatment consisted of surgical

resection. Interestingly, no recurrence or progression to more aggressive lymphoproliferative disease was documented, stressing the usually benign behavior of NLH.

AMYLOIDOSIS

Amyloidosis is characterized histopathologically by tissue infiltration with fibrillar protein with a β -sheet structural conformation, specifically stained by Congo red dye with a yellow-green birefringence under polarized light.¹⁶⁰ Amyloidosis has a highly variable presentation and may manifest in the lung as either parenchymal nodules (eFigs. 54-33 through 54-36) or masses.¹⁶⁰ Pulmonary amyloidosis may be localized to the lung or be associated with systemic amyloidosis.

Pulmonary nodules usually consist of AL (“amyloid light chain”) amyloid, which is the most common subtype of amyloidosis deposition.¹⁶⁰ AL amyloidosis is primary in more than 80% of cases and associated with inflammatory or lymphoproliferative disease in 20% of cases. AL amyloidosis develops as a result of the abnormal production of light immunoglobulin chains, often of lambda isotype. AL amyloidosis may be either systemic (e.g., in myeloma) or localized (e.g., in primary pulmonary lymphoma), with mild pulmonary interstitial (especially vascular) involvement that is usually asymptomatic.¹⁶¹ Serum and/or urinary monoclonal gammopathy is frequent.¹⁶²

Pulmonary nodular amyloidosis has been observed in patients in their seventh decade, without gender predominance. Patients are usually asymptomatic. Association with Sjögren’s syndrome has been reported.¹⁶³ Radiologically, pulmonary nodules are rounded and sharply delimited (see eFig. 54-34). Most nodules are peripheral. The nodules may range from 5 mm to more than 15 cm, may be solitary or multiple, and may be calcified. Nodules have shown increased activity on PET scans and may thus mimic bronchogenic carcinoma,¹⁶⁴ although lack of FDG avidity is also seen (see eFig. 54-35F and G). Other unusual imaging patterns may rarely be encountered (see eFigs. 54-35A-D and 54-36). Fine-needle biopsy may provide a pathologic diagnosis.¹⁶⁵ Pulmonary amyloid nodules may remain stable for years,¹⁶⁶ and surgical resection is proposed only in case of threatening symptoms. Recurrence is frequent after surgery.¹⁶⁷

NONAMYLOIDOTIC MONOCLONAL IMMUNOGLOBULIN DEPOSITION DISEASE

Nonamyloidotic monoclonal immunoglobulin deposition disease is more rare than amyloidosis and presents with deposits that are not stained by Congo red dye and do not demonstrate birefringence under polarized light.¹⁶⁸ These deposits most often consist of light chains, frequently kappa, or more rarely of single heavy chains or of mixed light and heavy chains.¹⁶⁸ The lung is a very unusual location.¹⁶⁹⁻¹⁷¹ Pulmonary nonamyloidotic monoclonal immunoglobulin deposition disease most frequently presents as multiple parenchymal nodules or, less frequently, as multiple cysts; deposition is usually limited to the lung without systemic involvement. Approximately half of the cases are associated with hematologic malignancies. Treatment of any underlying hematologic disease usually leads to regression of the monoclonal peak but has little effect on existing deposits. Pulmonary nonamyloidotic monoclonal immunoglobulin deposition disease may benefit from lung transplantation in cases of severe respiratory failure and in the absence of an underlying hematologic disorder.¹⁷⁰

PULMONARY LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis (LCH) is a heterogeneous disease defined by the proliferation of Langerhans cells, corresponding to CD1a-positive histiocytes exhibiting Birbeck granules on electron microscopy.^{172,173} These cells of dendritic lineage derive from CD34-positive bone marrow stem cells. If the lung is the sole location of the disease, it is called “pulmonary LCH.” In less than 15% of cases, LCH is associated with multisystem disease, corresponding to “acute disseminated LCH” involving the lung as well as the bone, the skin, and the pituitary gland.¹⁷⁴ The pathogenic concepts about LCH mostly involve an uncontrolled immune response to a yet undetermined stimulus, leading to the recruitment of Langerhans cells in the lung parenchyma. Smoking exposure is found in the majority of patients developing pulmonary LCH and is thought to stimulate this process in the bronchiolar epithelium.¹⁷⁵ The true nature of LCH remains elusive. Strongly favoring the hypothesis of a neoplastic disorder is the observation that Langerhans cells, isolated from patients with either pulmonary or disseminated LCH, are clonal.¹⁷⁶ An activating *BRAF* mutation, similar to that observed in melanoma, may be identified in LCH pulmonary nodules.¹⁷⁷ However, the limited proliferation of Langerhans cells, the absence of cellular atypia, the low number of Langerhans cells in high-stage lesions, and the possibility of spontaneous regression argue against a cancerous nature of LCH.

Pathologically, LCH lesions are made of Langerhans cells that proliferate and aggregate to form stellate nodules in the interstitium, with a bronchiolocentric pattern and linear distal and proximal spread. High-stage lesions are characterized by disappearance of Langerhans cells, increased amounts of fibrosis, and cavitation of the nodules leading to cyst formation.¹⁷²

Clinically, pulmonary LCH develops in young smokers who present with nonspecific respiratory symptoms, including dyspnea, cough, and chest pain. Pneumothorax may herald the disease in 15% of patients; 10% to 25% of patients

are asymptomatic. The most typical imaging feature is the combination of pulmonary multiple cysts and micronodules sparing the lower zones of the lung.¹⁷²⁻¹⁷⁴ Nodules, ranging from 5 mm to 2 cm in size, are centrilobular and may be solid or cavitated (eFig. 54-37A and B) with smooth or irregular margins. LCH is an active process, with predominant nodular aspect at early stages of the disease (see eFig. 54-37A and B), evolving to cavitated nodules, cysts of variable wall thickness (see eFig. 54-37C), and confluent cystic lesions over time (see eFig. 54-37D). Lesions of different age are usually observed. Rarely, pulmonary LCH presents as a single nodule, localized consolidation, or mediastinal disease.

Whereas the typical clinical-radiologic presentation may be virtually diagnostic for pulmonary LCH, pulmonary biopsy may be required in case of a tumor-like nodular or atypical (eFig. 54-38) presentation. Open lung biopsy is usually performed in patients with pneumothorax who require surgical intervention. Increased uptake on PET may suggest lung cancer; in a recent study of 11 patients, nodular lesions exhibited hyperavidity, with maximum standardized uptake values ranging from 2 to 18.¹⁷⁸ PET might be useful in the follow-up of the activity of the disease and is the subject of current research. Smoking cessation may lead to regression in as many as 25% of patients. No other treatment has been confirmed to be useful in pulmonary LCH, which may also regress spontaneously. Patients with progressive or multiorgan disease may benefit from chemotherapy with cladribine, which produced a 75% objective response rate in a landmark study of 13 patients.¹⁷⁹⁻¹⁸⁰ Supporting the neoplastic hypothesis, pulmonary LCH can recur following lung transplantation.

LESSONS LEARNED FOR THE MANAGEMENT OF RARE PRIMARY PULMONARY TUMORS

GENERAL ISSUES

The main differential diagnosis of rare pulmonary tumors is lung cancer. The absence of a tobacco-smoking history, especially in men, is more frequently seen for rare lung tumors and pseudotumors than for bronchogenic carcinoma (60% vs. 15%, respectively). Young age at diagnosis is another feature to consider, because more than 50% of pseudotumors present before the fourth decade. Given the frequent initial suspicion of lung cancer, most patients undergo complete oncologic workup. The PET scan may frequently be positive in pseudotumors, tending to support the presumptive diagnosis of lung carcinoma. Preoperative biopsies and intraoperative frozen sections may not be sufficiently representative of the tumor to ensure accurate histopathologic diagnosis, especially in biphasic or composite tumors, for which small-size samples may identify only one cellular component. Sophisticated pathologic studies, including flow cytometry and molecular and cytogenetic analysis, may have a critical role in diagnosis (evaluation of tumor grade) as well as in therapeutics, such as for lymphoma, IMT, or sarcomas. Frozen specimen collection and storage is mandatory to preserve the tumor for additional analyses.

DISTINGUISHING PRIMARY TUMORS FROM METASTASES

In making the diagnosis of a rare primary lung tumor, one must also consider the fact that most lung tumors with unusual histology represent metastases from extrapulmonary tumors, not primary tumors. The main criteria favoring metastases include a prior history of extrathoracic tumor and the finding of multiple pulmonary lesions. PET scanning may also be helpful, assuming that the metabolic features of each rare tumor subtype are sufficiently well described. The primary pulmonary nature of some rare tumors may actually be difficult to establish, either because of early systemic spread, as for EHE, which presents with synchronous pulmonary and hepatic lesions in 20% of cases, or because of an ectopic origin, as for melanoma or Hodgkin disease, for which a primary pulmonary origin is highly controversial.

GENERAL THERAPEUTIC MANAGEMENT

In many cases, initial surgical resection provides the correct diagnosis and the first step of the therapy. However, preoperative diagnosis remains important for specific subtypes, such as lymphoma, for which extensive resection is not recommended, and for sarcoma, which usually does not spread to the mediastinal lymph nodes and thus would not require nodal resection. Surgical biopsy may be required to obtain sufficient tissue material for extensive pathologic and molecular diagnoses, especially when clinical-radiologic presentation is not typical of neoplastic or non-neoplastic disease.

Finally, three main clinical scenarios may arise in the course of evaluation of patients with rare lung tumors:

1. Surgical resection of a tumor assumed to be NSCLC was complete, and pathologic examination disclosed an unusual histopathologic subtype, such as carcinoid. In this case, no adjuvant therapy is recommended.
2. Specific clinical and radiologic signs led to recognition of a rare tumor, such as lymphoma or pulmonary artery sarcoma, followed by specific diagnostic and therapeutic management.
3. Surgery of a pulmonary mass initially thought to be NSCLC led to recognition of a rare tumor subtype, and therapeutic and prognostic implications are unknown. In those cases, decision of adjuvant treatment is based either on an NSCLC standard of care (e.g., to use radiotherapy in case of incomplete surgical resection) or on therapeutic strategies established for similar tumor subtype in other locations (as it is done for lymphoma and sarcoma).

In the absence of evidence-based recommendations, expert consensus is mandatory for selection of a specific therapeutic strategy, possibly based on strategies developed for lesions of similar histology arising in other anatomic locations. Molecularly targeted treatment may be useful. Also, these issues emphasize the need for multicenter collaboration to generate cohorts and to launch observational studies and clinical trials of rare lung tumors.

Key Points

- Rare lung tumors are mainly defined as uncommon lung tumors with unusual histology. Rare tumors account for less than 1% of all primary lung tumors, whereas they correspond to more than 100 different histologic entities.
- Some rare lung tumors are specific to the lung, whereas others represent tumors more frequently found in other organs which only rarely present in the lungs. Determining whether they are primary or metastatic is a major step in the diagnostic evaluation.
- Rare lung tumors may mimic lung carcinoma or benign orphan lung diseases because they may share clinical, imaging, pathologic, and even molecular features.
- The most frequent rare primary lung tumors are carcinoids, mucosa-associated lymphoid tissue lymphoma, and pneumoblastoma. Specific therapeutic recommendations are available for carcinoids and large cell neuroendocrine carcinoma. In other cases, expert consensus is mandatory to plan specific therapeutic strategies.
- Pseudotumors are currently restricted to a specific heterogeneous group of diseases characterized by a circumscribed fibrous tissue associated with inflammatory and myofibroblastic cells; inflammatory myofibroblastic tumor is the most frequent entity.

eFIGURE IMAGE GALLERY

eFigure 54-1 Primary pulmonary MALT lymphoma: solitary pulmonary nodule. **A**, Frontal chest radiograph shows a nonspecific, solitary, lobulated right upper lobe pulmonary nodule (*arrow*). **B** and **C**, Axial enhanced chest CT scans displayed in lung windows show rapid growth of the nodule (*arrows*) over a 3-month period. **D** and **E**, PET and fused PET imaging obtained at nearly the same time as the CT studies (**B** and **C**) show marked metabolic activity within the nodule (*arrows*). Percutaneous transthoracic fine-needle aspiration and core biopsy showed pulmonary lymphoma. (Courtesy Michael Gotway, MD.)

eFigure 54-2 Primary pulmonary MALT lymphoma: multiple nodules. **A–D**, Axial chest CT scans displayed in lung windows show multiple ground-glass opacity nodules (*arrows*) associated with small lucent foci. One right lower lobe nodule (*arrowhead*) shows a solid component. Percutaneous transthoracic fine-needle aspiration and core biopsy showed pulmonary lymphoma. (Courtesy Michael Gotway, MD.)

eFigure 54-3 Pulmonary lymphomatoid granulomatosis. Axial chest CT scans displayed in lung (A) and soft tissue (B) windows show multiple, bilateral pulmonary nodules and a lingular mass, shown to represent pulmonary lymphomatoid granulomatosis at biopsy. (Courtesy Michael Gotway, MD.)

eFigure 54-4 Pulmonary lymphomatoid granulomatosis. A–C, Axial chest CT scans displayed in lung windows show multiple small nodules distributed along the bronchovascular bundles. A right middle lobe nodule (arrow) associated with an air bronchogram is present. Surgical lung biopsy showed pulmonary lymphomatoid granulomatosis. (Courtesy Michael Gotway, MD.)

Figure 54-5 Intravascular large cell lymphoma. **A–C,** Axial chest CT scans displayed in lung windows in a 46-year-old woman with sarcoidosis and systemic lupus erythematosus who complained of daily fever and progressive shortness of breath shows a right upper lobe nodule (*arrows*), growing rapidly over a 2-month period. A corticosteroid therapy burst for 1 week was initiated in addition to the patient's baseline daily dose of 40 mg prednisone, but the patient's complaints persisted following return to the baseline therapy. **D–G,** Axial chest CT scans after return to the baseline prednisone dose of 40 mg shows interval development of multiple, bilateral areas of consolidation and nodularity. A surgical lung biopsy of the right upper lobe nodule, evidenced by right upper lobe suture (*arrow*), was performed. **H,** CD31 stain for endothelial cells outlines pulmonary vessels (brown lined areas, *arrowheads*). Note intravascular tumor cells consistent with intravascular large B-cell lymphoma. (**H,** Original magnification $\times 40$.) (Images courtesy Cristian Jivcu, MD, Cardio-Pulmonary Associates, Monterey, CA.)

Figure 54-6 Pulmonary Hodgkin disease. **A,** Frontal chest radiograph in a 33-year-old woman shows a poorly defined right upper lobe nodule (*arrow*). Right paratracheal lymph node enlargement is also visible (*arrowhead*). **B,** Axial chest CT displayed in lung windows shows the poorly defined right upper lobe nodule (*arrow*) associated with a bronchus. The enlarged right paratracheal lymph node (*arrowhead*) is visible. **C,** Prone CT image obtained during transthoracic fine-needle aspiration and core biopsy. Material retrieved at this procedure did not allow a specific diagnosis. Subsequent surgical excision of the right upper lobe nodule revealed Hodgkin lymphoma. (Courtesy Michael Gotway, MD.)

eFigure 54-7 “Typical” carcinoid tumor: hilar mass. **A**, Frontal chest radiograph shows a circumscribed left hilar mass (*arrows*). **B** and **C**, Enhanced axial chest CT scans shown in soft tissue windows. **D**, Sagittal lung window shows an enhancing mass (*arrows*) arising from and obstructing the left lower lobe bronchus. Calcification (see *arrows*) is present within the mass. (Courtesy Michael Gotway, MD.)

eFigure 54-8 “Typical” carcinoid tumor: endobronchial lesion without postobstructive changes. Axial (**A–D**) and sagittal (**E**) unenhanced chest CT images show a small, circumscribed opacity (*arrows*) attached to the medial aspect of the cranial right lower lobe bronchus, unassociated with postobstructive pneumonia or atelectasis. Bronchoscopy and biopsy proved carcinoid tumor. (Courtesy Michael Gotway, MD.)

eFigure 54-9 Atypical carcinoid tumor. A–C, Axial enhanced chest CT scans displayed in soft tissue windows show extensive mediastinal lymph node enlargement (A and B, arrows) associated with a right middle lobe atypical carcinoid tumor (C, arrowhead). The appearance is indistinguishable from bronchogenic malignancy. (Courtesy Michael Gotway, MD.)

eFigure 54-10 “Typical” carcinoid tumor: somatostatin (octreotide) scintigraphy. Axial enhanced chest CT scans displayed in soft tissue (A) and lung (B) windows show a circumscribed soft tissue mass (*) in the right middle lobe, closely associated with bronchi (B, arrowhead), proven to represent typical carcinoid tumor. C, Coronal planar octreotide scan shows tracer uptake within the right middle lobe lesion (arrow). Normal physiologic uptake is seen within the liver (L) and spleen (S). (Courtesy Michael Gotway, MD.)

eFigure 54-11 Large cell neuroendocrine neoplasm. **A**, Frontal chest radiograph in a patient with biopsy-proven large cell neuroendocrine neoplasm shows a large right upper lobe mass. **B** and **C**, Axial chest CT scans displayed in soft tissue windows show a heterogeneous right upper lobe mass with foci of faint internal hyperattenuation. The appearance is nonspecific and indistinguishable from bronchogenic malignancy. (Courtesy Michael Gotway, MD.)

Figure 54-12 Mucoepidermoid carcinoma. Frontal (A) and lateral (B) chest radiographs in a young woman with mucoepidermoid carcinoma show the classic chest radiographic appearance of left upper lobe collapse. Left para-aortic lymphadenopathy (C, arrow) is present. C–E, Axial enhanced chest CT scans displayed in soft tissue windows show left upper lobe collapse and reveal the obstructing lesion (D and E, arrowheads). F, Coronal reformatted image displayed in an intermediate window again shows complete left upper lobe collapse as well as the obstructing lesion within the left upper lobe bronchus (arrowhead). G and H, Bronchoscopic images show the mucoepidermoid tumor completely obstructing the left upper lobe bronchial orifice. (Courtesy Michael Gotway, MD; case by Ewa Lupa-Laskus, MD, Arizona Pulmonary Specialists, Ltd, Scottsdale, AZ.)

eFigure 54-13 Primary pulmonary leiomyosarcoma. **A** and **B**, Axial enhanced chest CT scans show a large peripheral lung mass associated with a small left pleural effusion. A prominent vessel (**A**, arrowhead) is seen within the mass. **C–F**, Coronal MR images show a heterogeneous mass (**M**) with intermediate signal intensity, which reflects the relatively cellular and fibrotic nature of the lesion, arising from the peripheral left lung (**L**). Some areas of cystic change (the hyperintense foci) are present within the mass. The pulmonary origin of the mass, rather than pleural origin, is suggested by the visible “claw” of lung tissue (**E** and **F**, arrowheads) surrounding a portion of the lesion. A moderate left pleural effusion (*) is present. (Courtesy Michael Gotway, MD.)

eFigure 54-14 Primary pulmonary leiomyosarcoma: endobronchial origin. **A**, Frontal chest radiograph shows a poorly defined medial left upper lobe nodule (arrow). **B** and **C**, Axial chest CT scans displayed in lung windows show a circumscribed lesion (arrow) in the left upper lobe that could be traced to the apical-posterior segmental left upper lobe bronchus; note presence of hyperlucency distal to the lesion (arrowheads), representing postobstructive air trapping. **D**, Fused axial PET image shows intense metabolic activity within the lesion (arrow). (Courtesy Michael Gotway, MD.)

eFigure 54-15 Pulmonary artery sarcoma: imaging appearances. **A**, Frontal chest radiograph shows a smoothly enlarged left pulmonary artery associated with left lung oligemia. Whereas pulmonary embolism can result in similar findings, emboli rarely produce findings of this magnitude. **B–E**, Axial enhanced chest CT scans in two patients show a large hypoattenuating lesion completely filling the right pulmonary artery (**A**, arrow), associated with pulmonary infarction (**A**, arrowheads). The second patient (**C–E**) shows a large lesion simulating a saddle pulmonary embolism (arrows). Both patients were hemodynamically stable and presented with subacute shortness of breath; such a presentation would be exceedingly unlikely if pulmonary emboli were the cause of these large, obstructing central intravascular lesions. The full extent of the intravascular lesion and its resemblance to thromboembolic disease is demonstrated in [Video 54-1](#). **F** and **G**, Axial PET scan (same patient as in **C–E**) shows intense hypermetabolic activity within the intravascular lesion, consistent with neoplasm. (Courtesy Michael Gotway, MD.)

Figure 54-16 Pulmonary artery sarcoma: MR appearance. Axial double-inversion recovery T1-weighted image (**A**) and axial enhanced fast spoiled gradient echo images (**B** and **C**) show a soft tissue mass completely filling the left pulmonary artery. Note the faint internal enhancement visible within the intravascular lesion in **B**. (Courtesy Michael Gotway, MD.)

eFigure 54-17 Pulmonary artery sarcoma: tumor recurrence. **A–C**, Axial enhanced chest CT scans show right peribronchial lymph node enlargement (**A**, *double arrows*) associated with a tumor mass arising from the right lower lobe artery (**B**, *arrow*). Note the small focus of hyperattenuation present within the primary tumor (**B**, *arrowhead*). The lesion was an osteosarcoma arising with the pulmonary artery. Just over a year following right pneumonectomy, ossified metastatic nodules (**C**, *arrowhead*) appeared within the left lung. **D** and **E**, Left pulmonary artery sarcoma (**D**, *arrow*) with recurrence (**E**, *arrowhead*) 1 year after left pneumonectomy. (Courtesy Michael Gotway, MD.)

eFigure 54-18 Pulmonary hemangioendothelioma. A–E, Axial chest CT scans in a 39-year-old woman with cough and hemoptysis displayed in lung windows show multiple, bilateral, variably sized ground-glass opacity nodules with foci of solid nodular internal opacity centrally (*arrows*). One right lower lobe lesion shows peripheral consolidation surrounding ground-glass opacity with a centrally located solid nodular focus (**E**, *arrowhead*). Surgical lung biopsy proved pulmonary hemangioendothelioma. The lesions have been stable for 1 year during follow-up. (Courtesy Michael Gotway, MD.)

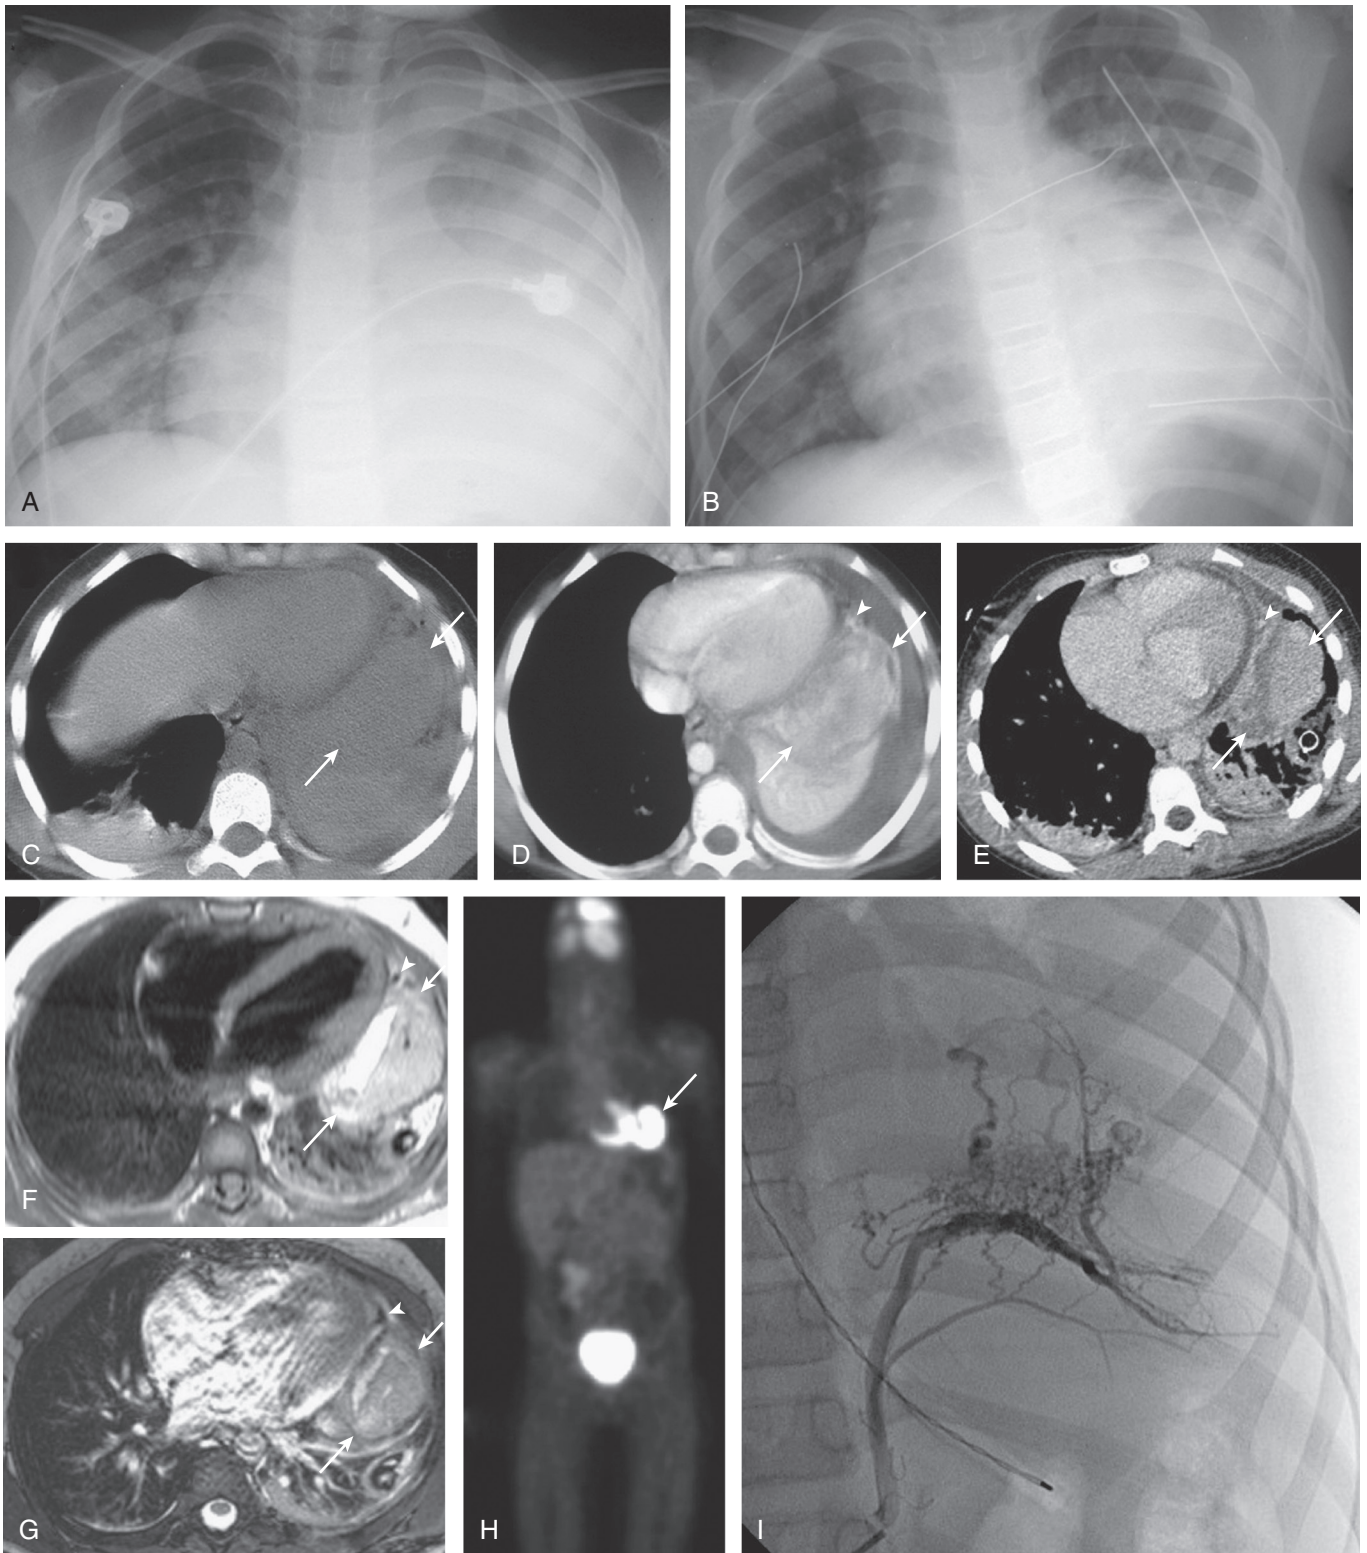

Figure 54-19 Inflammatory myofibroblastic tumor. **A**, Frontal chest radiograph obtained in an 8-year-old boy after being struck by an automobile shows a large left pleural effusion and basal predominant left lung opacity. **B**, Frontal chest radiograph obtained after insertion of a surgical thoracostomy tube shows removal of the pleural fluid. During the placement of this tube, the surgeon noted a lesion in the left chest and obtained a small biopsy specimen, but profuse bleeding prevented further assessment. Axial unenhanced (**C**) and enhanced (**D**) chest CT shows a left lower anterior chest mass (arrows); the mass shows intense enhancement following intravenous contrast administration. A large vessel (**D**, arrowhead) is present in the anterior mediastinum adjacent to the mass. **E**, Axial enhanced multislice chest CT again shows the mass (arrows) and prominent mediastinal vessel (arrowhead). This examination was obtained to search for aberrant systemic arterial supply on the assumption that the lesion might represent a sequestration. No systemic arterial supply arising from the thoracic aorta was seen, but the examination was not extended into the upper abdomen to evaluate the cranial abdominal aorta. Axial T1-weighted (**F**) and axial gradient echo (**G**) MR images show that the mass (arrows) contains high signal in T1-weighted and intermediate-to-low signal on gradient echo imaging, consistent with hemorrhage. The hypointense structure in the mediastinum adjacent to the mass (arrowheads) represents a flow void within a large vessel. **H**, Coronal PET image shows intense metabolic activity within the lesion (arrow). **I**, Coronal preoperative angiogram shows aberrant systemic arterial supply to the mass derived from the cranial abdominal aorta; this vessel was embolized to decrease intraoperative blood loss. Inflammatory myofibroblastic tumor was confirmed following surgical resection, and the lesion was noted to be highly vascular and to have invaded the mediastinum at surgery, with the venous drainage of the mass corresponding to the large anterior mediastinal vessel seen on CT (**D** and **E**) and MRI (**F** and **G**). (From Gotway MB, Dawn SK: An unusual cause of a pulmonary mass. *Clin Pulmon Med* 11:266–268, 2004.)

eFigure 54-20 Multicentric inflammatory myofibroblastic tumor. **A–D,** Axial chest CT scans displayed in lung windows show multiple, variably sized, poorly defined nodules (*arrows*). **E and F,** Axial PET images show mildly increased metabolic activity within several of the nodules (*arrows*). The imaging features are ultimately nonspecific, and surgical excision was required to establish the diagnosis. (Courtesy Michael Gotway, MD.)

eFigure 54-21 Mediastinal fibrosis: noncalcified mediastinal soft tissue. **A–D,** Axial enhanced chest CT scans show infiltrating soft tissue (*) throughout the mediastinum, associated with occlusion of the superior vena cava, which prompted stent placement (*arrows*). The venous compression resulted in extensive venous collateral vessel formation (*arrowheads*). (Courtesy Michael Gotway, MD.)

eFigure 54-22 Mediastinal fibrosis: venous infarction and noncalcified mediastinal soft tissue. Axial enhanced chest CT scans displayed in lung (A and B) windows show subpleural right upper lobe opacities (arrowheads) representing pulmonary infarction, resulting from pulmonary venous compression. Mediastinal soft tissue (C and D, arrowheads) is seen compressing the right pulmonary artery. (Courtesy Michael Gotway, MD.)

eFigure 54-23 Pulmonary hamartoma: nonspecific nodule. A, Frontal chest radiograph shows a nonspecific right perihilar pulmonary nodule (arrow). B, Fused axial PET scan shows no significant FDG uptake within the nodule (arrow). C, Prone CT obtained during transthoracic fine-needle aspiration and core biopsy shows no fat or calcium within the lesion. The biopsy established the diagnosis. (Courtesy Michael Gotway, MD.)

Figure 54-24 Pulmonary hamartoma: chondroid calcification. **A**, Focused frontal chest radiograph shows a left apical nodule (*arrow*) associated with internal calcification. Note that the pattern of calcification can be described as “rings and arcs,” which is consistent with calcification within cartilage. **B**, Axial unenhanced chest CT confirms the presence of calcium within the nodule (*arrow*) seen at chest radiography (**A**). This pattern of calcification is reminiscent of a popped kernel of popcorn; hence, the pattern of chondroid calcification is also often referred to as “popcorn” calcification. **C** and **D**, Axial chest CT scans show another hamartoma (*arrows*) with the characteristic chondroid calcification pattern. Axial enhanced chest CT (**E**) and axial fused PET scan (**F**) show typical chondroid calcification within a pulmonary nodule (*arrows*), consistent with hamartoma. The nodule (*arrows*) shows no significant metabolic activity. (Courtesy Michael Gotway, MD.)

Figure 54-25 Pulmonary hamartoma: “giant” chondroid hamartoma. Axial chest CT shows a very large right lower lobe mass, but the lesion contains typical chondroid calcification. The lesion was resected due to its large size and was found to represent hamartoma. (Courtesy Michael Gotway, MD.)

eFigure 54-26 Pulmonary hamartoma: intralesional fat. **A**, Axial chest CT, which was obtained for evaluation of a nodule that was incidentally detected on chest radiography, shows a nonspecific medial right upper lobe nodule. No calcification is present. A few hypoattenuating areas (*arrowheads*), suggesting intralesional fat, were noted, but were not sufficiently visualized to allow a confident noninvasive diagnosis of hamartoma. The lesion was resected and hamartoma containing fat was confirmed. **B**, Axial chest CT, which was obtained in another patient for evaluation of a nodule that was incidentally detected on chest radiography shows a right lower lobe nodule that clearly contains low attenuation tissue (*arrowhead*); the attenuation coefficient within the hypoattenuating area was -65 HU, indicating the presence of fat within the lesion and consistent with hamartoma. (Courtesy Michael Gotway, MD.)

eFigure 54-27 Pulmonary hamartoma: cystic chondroid hamartoma. Axial chest CT shows a nonspecific left lower lobe thin-walled cystic lesion. This lesion had expanded slowly over a 7-year period, eventually causing symptoms and prompting resection, at which time the diagnosis of cystic chondroid hamartoma was established. (Courtesy Michael Gotway, MD.)

eFigure 54-28 Minute pulmonary meningothelial-like nodules. **A** and **B**, Axial chest CT scans displayed in lung windows obtained for evaluation of a right upper lobe nodule confirm the presence of a small right upper lobe nodule (**A**, *arrow*), as well as numerous very small pulmonary nodules in the upper lobes bilaterally. **C** and **D**, Axial chest CT scans displayed in lung windows obtained following surgical resection of the right upper lobe nodule (pathologically confirmed adenocarcinoma; *arrowheads* show site of postoperative change) again show the small bilateral pulmonary nodules. These nodules were seen in the right upper lobe wedge resection specimen and conformed to represent minute pulmonary meningothelial-like nodules. (From Sellami D, Gotway MB, Hanks DK, Webb WR: Minute pulmonary meningothelial-like nodules: thin-section CT appearance. *J Comput Assist Tomogr* 25:311–313, 2001.)

eFigure 54-29 Tracheobronchial papillomatosis: typical chest radiographic and CT findings. **A**, Frontal chest radiograph in a patient with tracheobronchial papillomatosis shows several variably sized nodules (*arrows*) bilaterally. **B**, Axial chest CT displayed in lung windows shows the typical combination of nodules (*arrows*) and cysts (*arrowheads*). (Courtesy Michael Gotway, MD.)

eFigure 54-30 Tracheobronchial papillomatosis: early disease. **A** and **B**, Axial chest CT scans displayed in lung windows show small centrilobular nodules (*arrowheads*) and thin-walled cavities (*arrows*) in the superior segment of the right lower lobe (a relatively dependent distribution). (Courtesy Michael Gotway, MD.)

Figure 54-31 Tracheobronchial papillomatosis: **A, B, D, and E,** Axial chest CT scans displayed in lung windows show relatively thin-walled, variably sized cysts (*arrowheads*) and nodules (*arrows*). **C,** Axial enhanced chest CT displayed in soft tissue windows shows circumferential tracheal wall thickening (*double arrowheads*). (Courtesy Michael Gotway, MD.)

Figure 54-32 Tracheobronchial papillomatosis: progressive disease with malignant transformation. **A–F,** Axial chest CT images displayed in lung windows show progressive cyst and cavity enlargement with increasing nodularity related to the cyst walls. **A and B,** Axial chest CT scans show mostly thin-walled cyst formation (*arrowheads*) with relatively mild nodularity (**B, arrow**). Axial chest CT obtained just over 1 year after **A** and **B** shows enlarging cysts (**C and D, arrowheads**) and marked increase in nodular opacity related to the posterior segment right upper lobe bronchus (**D, arrow**). **E and F,** Axial chest CT scans performed just over 2 years following **A** and **B** show further enlargement of pulmonary cysts and cavities (*arrowheads*), with marked increase in cavitory nodular right lung opacity (*arrows*). **G,** Gross right lung specimen following pneumonectomy shows cystic change (*arrowhead*) with extensive cavitation with internal mural nodularity (*arrows*). The mural nodular opacity represents squamous cell carcinoma development. (**A to F,** Courtesy Michael Gotway, MD.)

eFigure 54-33 Pulmonary amyloidosis: solitary pulmonary nodule. **A**, Frontal chest radiograph shows an oblong, nonspecific right lower lobe nodule (*arrow*). Axial enhanced chest CT scans displayed in lung (**B**) and soft tissue (**C**) windows show a lobulated, noncalcified right lower lobe nodule (*arrows*). The imaging features are nonspecific, but transthoracic fine-needle aspiration and core biopsy revealed that the nodule was due to amyloid. (Courtesy Michael Gotway, MD.)

eFigure 54-34 Pulmonary amyloidosis: multiple pulmonary nodules. **A–D**, Axial chest CT scans displayed in lung windows show multiple variably sized bilateral pulmonary nodules (*arrows*), which were shown on biopsy to represent amyloidosis. (Courtesy Michael Gotway, MD.)

Figure 54-35 Pulmonary amyloidosis: nodules, cysts, and nodule-within-cyst morphology. **A–D,** Axial chest CT scans displayed in lung windows show multiple thin-walled cysts (*arrows*), some of which contain faint internal nodular opacity. A solid nodule (**C**, *arrowhead*) is present in the medial right middle lobe. **E,** Axial chest CT displayed in soft tissue shows no evidence of calcification within one nodule located in the medial right middle lobe nodule (*arrowhead*). **F and G,** Axial fused PET scan shows active tracer utilization within the medial right middle lobe nodule (**F**, *arrowhead*), but not within the right basal cystic lesion. No tracer utilization was present in the other cystic foci elsewhere. Surgical excision of several of the cystic and nodular foci showed amyloidosis. (Courtesy Michael Gotway, MD.)

eFigure 54-36 Light chain deposition disease. **A** and **B**, Axial chest CT scans displayed in lung windows show numerous small, circumscribed nodules distributed along interlobular septae and fissural surfaces. The nodule distribution appears perilymphatic, and sarcoidosis was the working diagnosis. Bronchoscopy with transbronchial biopsy established the diagnosis of light chain deposition disease. (Courtesy Michael Gotway, MD.)

eFigure 54-37 Langerhans cell histiocytosis. **A** and **B**, Axial chest CT scans displayed in lung windows performed in a 17-year-old patient show features consistent with relatively “early” Langerhans cell histiocytosis: numerous small nodules, some showing cavitation (**B**, arrowhead), and a few developing bizarre-shaped cysts (**A**, arrow). **C**, Axial chest CT displayed in lung windows performed in a 30-year-old smoker shows features consistent with more developed Langerhans cell histiocytosis: prominent, bizarre-shaped cysts (arrow), with a few small solid and cavitating (arrowhead) nodules. **D**, Axial chest CT displayed in lung windows performed in a 55-year-old smoker shows features consistent with relatively “late,” or “burned-out,” Langerhans cell histiocytosis: innumerable small cystic areas resembling pulmonary emphysema (which is often coexistent). (Courtesy Michael Gotway, MD.)

eFigure 54-38 Atypical imaging manifestation of Langerhans cell histiocytosis. **A–D**, Axial chest CT images displayed in lung windows show a few small nodules (**A** and **B**, arrows) with a relatively thin-walled cavitory lesion (**C** and **D**, arrowheads) in the right middle lobe. The imaging features are nonspecific and the diagnosis was established through video-assisted thoracoscopic wedge resection of several of the pulmonary opacities. (Courtesy Michael Gotway, MD.)

INTRODUCTION

The lung is a common site for metastasis of malignant tumors from other organs. Logic would suggest that the lung is such a common destination for metastasis because it alone receives the entire cardiac output.¹ Indeed, this likely does play a role in the eventual seeding of the lungs when cancers metastasize via the hematogenous route. However, a more detailed understanding of the molecular mechanisms dictating organ-specific metastases has made it clear that specific properties of the primary tumor and the microenvironment of the tissue of origin and of the lung play a significant role in directing the process of metastasis to the lung. Paget initially proposed what became known as the “seed and soil” hypothesis in 1889 based upon his observations of the nonrandom nature of breast cancer metastasis.² While we can now begin to define mechanisms of organ-specific metastases at a molecular level, we still lack therapeutic tools specifically aimed at preventing metastases.³ This chapter reviews the epidemiology of lung metastasis, advances in our knowledge of the pathophysiology of metastasis, approaches to help distinguish metastasis from primary lung cancer, advances in diagnostic methods, and treatment options that vary from palliation to curative surgery.

EPIDEMIOLOGY

Estimates of the incidence of lung metastasis among patients with cancer vary from 20% to 40%.^{1,4} However, estimates of the incidence of lung metastasis have limitations. Most series focus on a single tumor type as the origin of lung metastases. The incidence of lung metastasis also varies depending on the means used for detection and for follow-up; a lower incidence is reported if the metastases are detected by the presence of respiratory symptoms and rises progressively when metastases are detected by routine surveillance with chest radiographs or with *computed tomography* (CT) scans, or autopsy data. Not surprisingly, the detection of metastases for any given solid tumor type

will be greater when ¹⁸F-fluorodeoxyglucose positron emission tomography (PET) scanning is used as a method of surveillance.⁵ While reports of the proportion of cancers that metastasize to the lung vary, the lung is always among the most common sites of metastasis of solid tumors.⁴

CLINICAL HISTORY

Lung nodules or effusions developing in the context of an extrapulmonary neoplasm can either be *synchronous* (discovered at the same time as the primary tumor) or *metachronous* (discovered at some period after the initial solid tumor, either incidentally in the course of follow up of a prior malignancy or in the context of new pulmonary symptoms). Because of the large degree of reserve pulmonary function in most individuals, metastases to the lungs rarely produce symptoms, and even patients with a large metastatic tumor burden can present with minimal or no pulmonary symptoms. When nonspecific symptoms of cough, dyspnea, or chest pain and discomfort can be attributed to metastatic lesions, they usually result from either a very large tumor burden (Fig. 55-1), extensive lymphatic infiltration, airway involvement, or a large pleural effusion. The first clue to the presence of lung metastasis comes most commonly from surveillance radiographs in patients with known prior cancer. The most common presentation of lung metastasis is the finding of multiple nodules in the lower lobes. The finding of an incidental solitary pulmonary nodule as the first sign of an extrapulmonary neoplasm makes the distinction of metastasis from that of a primary lung tumor challenging. The physical examination is unlikely to disclose evidence of lung metastasis but, in the context of a solitary pulmonary nodule, the examination should include a search for malignancy elsewhere in the body (e.g., breast or abdominal masses, enlarged lymph nodes). Rarely, a metastasis can affect the larger central airways, producing localized wheezing, which an astute clinician discovers on auscultation. Malignant pleural fluid accumulation produces the physical findings of reduced breath sounds, a dull percussion note, and decreased tactile fremitus.

Figure 55-1 Typical appearance of metastatic disease. Axial (A) and coronal (B) chest CT displayed in lung windows of a patient with innumerable rounded lower lobe nodules and a prior history of melanoma. The pretest probability of metastases is so high in such a case that the oncologist may not require a tissue confirmation.

MECHANISM OF METASTASIS TO THE LUNG

When one considers that the lung receives the entire cardiac output, it is perhaps surprising that lung metastases are not even more common among patients with cancer. However, research has shown that the majority of cancer cells that circulate in the blood never result in a clinically overt metastatic focus,^{6,7} suggesting that mere access to the lung is not sufficient to lead to clinically evident metastasis. Additional mechanisms must therefore account for the propensity of certain tumors to seed distant organs preferentially.

One of the main processes involves expression of receptors that bind to ligands in metastatic sites. Chemokines are a group of small cytokines originally discovered as mediators of leukocyte trafficking. Chemokines mediate several important pathologic aspects of tumor biology, including angiogenesis, cell proliferation, invasion, and metastasis.⁸ The pattern of constitutive expression of chemokine receptors on cancer cells combined with expression of the corresponding chemokine ligands in various organs may be responsible for the organ-specific pattern of metastasis of a variety of solid tumor types, including breast, prostate, and lung cancer.⁹⁻¹¹ For example, the chemokine receptors CXCR4 and CCR7 are highly expressed in human breast cancer cell lines, in primary breast tumor samples, and in their metastases. The corresponding ligands for the CXCR4 and CCR7 receptors, CXCL12 and CCL21, are constitutively expressed in organs to which these tumors commonly metastasize (lung, brain, bone, and lymph nodes).¹¹ In breast cancer cell lines, signaling through the receptors CXCR4 or CCR7 promotes *in vitro* migration and invasion. Most interestingly, antibodies or small molecule antagonists directed against CXCR4 significantly impaired metastasis of breast cancer cells to regional lymph nodes and lung *in vivo*. In addition, malignant melanoma, which has a similar metastatic pattern as breast cancer but also a high incidence of skin metastases, showed high expression of the chemokine receptor CCR10 in addition to CXCR4 and CCR7. The ligand for CCR10 (cutaneous T-cell attracting chemokine, or CTACK/CCL27) is highly expressed in normal dermis.¹² In a study of metastasis of non-small cell lung

cancer, metastatic cells were found to be enriched for the expression of CXCR4 compared to cells from the primary tumors, suggesting that CXCR4-expressing cells had an advantage in reaching or surviving in the metastatic niche.¹⁰ Chemokine receptors on cancer cells, in concert with tissue-specific expression of their chemokine ligands, appear to have a critical role in determining the metastatic destination of circulating tumor cells.

Certain molecular processes may increase lung vascular permeability to metastatic cells. In an elegant study, transforming growth factor- β was shown to prime breast cancer cells for lung-specific metastasis by up-regulation of the gene *angiopoietin-like 4* (ANGPTL4).¹³ Transforming growth factor- β induction of ANGPTL4 in breast cancer cells enhanced their subsequent retention in the lungs but not in bone. Tumor cell-derived ANGPTL4 disrupted the pulmonary microvascular cell-cell junctions, increasing the permeability of lung capillaries and facilitating the passage of tumor cells into the lung parenchyma. In contrast, in the bone marrow sinusoids, which are normally more leaky microvascular beds, this mechanism does not confer an advantage.¹³

Other processes may help support the metastatic cell in its lung niche. In another elegant mouse study, tumor cells were shown to be preceded into the metastatic niche by *bone marrow derived cells* (BMDCs) that express the type 1 *vascular endothelial cell growth factor receptor* (VEGFR1+BMDC). These authors demonstrated that VEGFR1+BMDCs were hematopoietic progenitor cells that (1) arrived at the metastatic site before tumor cells, (2) accumulated in the target organ of metastasis following either injection of tumor cells or treatment with tumor cell conditioned media, and (3) established a premetastatic niche in a tumor-specific fashion (i.e., they established a permissive environment for metastasis in an organ-specific pattern that varied depending on the tumor type).

Finally, other processes may enhance lung-specific adherence. As illustrated by Brown and Ruoslahti,¹⁴ the protein, *metadherin*, was found by phage display to be present on the surface of metastatic breast cancer cells that preferentially allowed adherence to the pulmonary vascular endothelium.¹⁴ In summary, tissue-specific metastases arise in a nonrandom fashion determined by specific

molecular mechanisms that involve both tumor-derived soluble factors and microenvironment-specific ligand-receptor interactions.

A further refinement in our understanding of the mechanisms of metastasis comes from a study that examined isolated efferent blood from primary tumors in mice and found that primary tumors also shed tumor fragments consisting of both malignant cells and host stromal fibroblasts. Importantly, the viability of circulating malignant cells was nearly twofold higher in these heterotypic tumor fragments than in single tumor cells shed from the primary tumor. These chaperone stromal fibroblasts survived, proliferated, and conferred a survival advantage to lung metastatic deposits. When the investigators selectively depleted carcinoma-associated fibroblasts from mice after primary tumor removal, the growth of metastatic deposits was significantly inhibited. The study further demonstrated that human brain metastases, but not primary brain tumors, contained carcinoma-associated fibroblasts, supporting the hypothesis that the fibroblasts enhanced the metastatic malignant process. This elegantly designed and executed series of experiments, which required modern molecular techniques and lineage tracking of cells, brought the field back full circle to Paget's seed-and-soil hypothesis because, as the authors correctly point out, the tumor cells facilitate lung metastasis by "bringing their own soil."¹⁵ While these molecular insights have not yet led to specific interventions to prevent metastasis, such advances in the knowledge of molecular mechanisms that promote or facilitate organ-specific metastasis can be expected to drive the search for new treatments to prevent cancer metastasis. Metastases are nearly universally responsible for cancer mortality and, if metastases can be prevented or treated by novel strategies based on these molecular insights, survival with cancer (as opposed to a cure for cancer) is an attainable goal. A diagram illustrating potential mechanisms behind tissue specific metastasis to the lung from extrapulmonary malignancies is shown in Figure 55-2.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Given the range of diagnostic and therapeutic options in cases of known or suspected lung metastasis, patient care is optimal when delivered within the context of a multidisciplinary team. For example, when deciding whether to biopsy a lung nodule in a patient with a prior cancer, a chest physician is well served by speaking to the oncologist and/or the surgeon to learn whether a patient with metastatic cancer has therapeutic options and whether the results of a biopsy would alter those options. If a patient with a solitary nodule suspected to be an isolated lung metastasis is a surgical candidate and a complete resection is feasible, a preoperative tissue diagnosis may not change the treatment plan and, if so, should not be undertaken. Conversely, surgeons may prefer a preoperative tissue diagnosis to improve their discussion of risks, benefits, and alternatives with the patient. Surgeons may also prefer knowing whether a nodule is a metastasis or a primary lung cancer in planning the appropriate surgical procedure, either a

Figure 55-2 Illustration of molecular mechanisms that can drive lung specific metastasis from extrapulmonary malignancy. A, The primary tumor can release (1) single tumor cells, (2) soluble substances such as angiopoietin-like 4 (ANGPTL4), and (3) heterotypic tumor fragments, which enjoy a survival advantage that renders them more likely to reach the lung (4). In the lung, tumor-derived ANGPTL4 creates a microvascular bed that is leaky and conducive to entry of tumor cells in the lung (5). **B,** Tumor cells bearing CXCR4, the receptor for the CXC chemokine CXCL12, are preferentially attracted to organs that constitutively produce CXCL12.

lobectomy or an anatomic segmentectomy. For these and other reasons, the management of these patients is best served when clinicians are readily able to communicate patient-specific concerns to one another, such as in a multidisciplinary conference.

In general, the patient with a prior history of cancer and suspicion of a lung metastasis should be managed with knowledge of several interacting factors: the type of prior cancer, its natural history, its propensity to cause lung metastasis, its sensitivity to systemic or radiation therapy, and the number and location of lung nodules. A decision to biopsy should take into account the likelihood of an alternative diagnosis and whether the results of the biopsy will change the management options. The diagnostic possibilities for a lung nodule or multiple nodules in the patient with

a history of cancer vary with the type of prior cancer. For example, the implications of finding a cavitary nodule in a patient with prior leukemia after a bone marrow transplant are quite different from finding the same cavitary nodule in an individual with prior head and neck cancer. In general, the differential diagnosis of a lung nodule in a patient with prior cancer includes the same diagnoses found in the general population, with the obvious exception that metastatic disease must be considered as well. Both primary malignant and benign causes, including infectious and noninfectious etiologies, should be considered (Table 55-1).

DISTINGUISHING METASTASIS FROM PRIMARY LUNG TUMORS

When a nodule or nodules are discovered in a patient with a prior history of cancer, it is important to distinguish lung metastasis from a primary lung cancer because the treatment can be very different. Clues such as the type of prior cancer, radiologic characteristics of the nodule, and pathologic appearance of subsequent biopsy material can be used to guide treatment decisions. Multiple pulmonary nodules with smooth borders located in the lower (dependent) lobes are most likely to be metastatic based on clinical grounds alone. When a single nodule is the only evidence of metastasis, recognizing it as metastatic can be more difficult. In some instances, the type of prior cancer can provide a clue to the likelihood of a metastasis versus a primary lung cancer. In a retrospective study of patients with single pulmonary nodules and a prior history of cancer, multiple factors were examined as possible predictors for metastasis including the histologic characteristics of the original extrapulmonary neoplasm, patient age, and smoking history. Of 161 patients with solitary pulmonary nodules, 81 (50%) were determined to have a primary lung cancer; this outcome was more common in patients with a prior history of cancer of the head and neck, bladder, breast, cervix, bile ducts, esophagus, ovary, prostate, or stomach. Fifty patients (31%) were determined to have metastasis, a finding more common in patients with salivary, thyroid, and adrenal tumors, melanoma, and sarcoma. Primary

lung cancer or metastases were equally likely in patients with prior cancer of the colon, kidney, or uterus. In those with prior lymphoma or leukemia, there was a high proportion of patients with a benign diagnosis (6 of 14), perhaps reflecting the predisposition of these patients to infections.¹⁶ In total, 30 of 161 patients (19%) had nodules of a benign nature. The large percentage of benign diagnoses in this study by Quint and colleagues¹⁶ (1994–1999) contrasts with a larger but much older study by Cahan and associates¹⁷ (1940–1975) in which only 11 of 800 patients (1.3%) had benign disease. The higher incidence of benign disease in the more recent study can probably be explained by two factors: (1) because of the greater use of CT scanning and thus higher rate of detection of nodules in the later study and (2) because the earlier study was a surgical series in which patients with a high pretest probability of benign disease may have been excluded. A consistent finding in these two studies representing nearly 40 total years from two large centers was the high proportion of patients with head and neck squamous or esophageal cancers in whom a primary lung cancer subsequently developed. Aerodigestive cancers share common risk factors, and the presence of a smoking history increases the likelihood that a solitary lung nodule in someone with a prior extrapulmonary neoplasm will prove to be a lung cancer. By understanding the data in these and other studies, clinicians can more accurately estimate the likelihood that a pulmonary nodule is a metastatic malignancy, a primary lung cancer, or benign.

PATHOLOGY

When a nodule is found to be malignant, the etiology of the nodule can be assessed by comparing the pathology of the prior cancer and the lung nodule. The pathologist's approach begins with a knowledge of the prior cancer, its stage and grade (if applicable), and the pretest likelihood of lung metastasis from a tumor with such characteristics. The gross and microscopic pattern of the possible metastasis may be sufficiently similar to the original primary tumor that the diagnosis is rendered easily. In many situations, the histology is not sufficiently distinctive to permit a differentiation between metastasis and primary lung cancer,¹⁸ and immunohistochemical stains are used to help guide the diagnosis (Table 55-2). Lung adenocarcinoma can be identified by specific immunohistochemical markers including cytokeratin-7, *thyroid transcription factor 1* (TTF1, see Fig. 19-4B), and napsin.^{18,19} For example, cytokeratin-7 can be useful for distinguishing adenocarcinoma of the lung from colon cancer metastasis, with cytokeratin-7 favoring lung and cytokeratin-20 favoring a colon primary.¹⁸ TTF1, a nuclear transcription protein expressed in embryonic and adult epithelial cells of the lung and thyroid,²⁰ is detected in 75% of lung adenocarcinomas, but rarely detected in other adenocarcinomas that commonly metastasize to the lungs except for thyroid cancer.²⁰ Napsin is an aspartic proteinase that is present in lung and kidney epithelial cells, and is a newer marker for lung adenocarcinoma with similar sensitivity but slightly greater specificity for lung origin than TTF1. Markers specific for other tumors can be used to identify lesions as metastatic; for example, breast cancers can generally be identified if they maintain their original pattern of staining for estrogen receptor or Her-2/Neu, melanomas

Table 55-2 Immunohistochemical Stains Useful for Distinguishing Primary Lung Cancer from Metastatic Cancer Secondary to an Extrapulmonary Primary Cancer

Cancer	Positive Markers	Negative Markers
Lung	CK7, TTF1,* SP-A, SP-B, Napsin,* p63 [†]	CK20, PAX2, PAX8
Colon	CK20	TTF1, Napsin
Bladder (urothelium)	S100P, GATA3	TTF1, Napsin
Breast	ER, PR, HER2/neu	TTF1, Napsin
Prostate	PSA, prostatic acid phosphatase	TTF1, Napsin
Melanoma	HMB45, S100, tyrosine hydroxylase	Cytokeratin [‡]
Thyroid	TTF1, thyroglobulin	Napsin
Germ cell	Alpha-fetoprotein	TTF1, Napsin
Renal cell	PAX2, PAX8, RCCma	TTF1, Napsin

*Adenocarcinoma specific.

[†]Squamous carcinoma specific.[‡]Fewer than 10% of melanoma metastases stain positively for cytokeratin.

CK, cytokeratin; ER, estrogen receptor; PAX2, paired box gene; PR, progesterone receptor; RCCma, renal cell carcinoma marker; TTF, thyroid transcription factor; PSA prostate specific antigen.

can be identified by S100 or HMB45 immunoreactivity, and renal carcinoma can be identified by immunostaining for the product of paired box 2 or 8 genes, *PAX2* or *PAX8*. Thus, when the primary tumor stains for specific markers, these stains can be useful for identifying a lesion as a metastasis. Squamous carcinoma presents a particular challenge for distinguishing between a metastasis and a primary lung carcinoma, because there are no markers currently capable of distinguishing between squamous tumors of lung origin and those from extrapulmonary epithelial tissues.

Molecular Classification

Progress in transcriptional and proteomic characterization of tumors has provided tools to assist in determining the nature of a lung nodule. Giordano and colleagues attempted to develop a molecular classification scheme to discriminate adenocarcinomas of the lung, colon, and ovary.²¹ They identified three groups of 20 differentially expressed genes that correctly identified the origins of all but 2 of 154 tumors.²¹ Other groups of investigators have proposed classifiers for a broader representation of tumors in an effort to categorize tumors diagnosed as carcinoma of unknown primary. Tothill and colleagues developed a gene array-based classifier using a microarray platform and validated with real-time polymerase chain reaction on 229 samples of known origin (a training set).²² This gene classifier was then able to assign a “tissue of origin” in 9 of 11 cases of carcinoma with unknown primary.²² They noted that the two specimens that the gene classifier failed to classify were actually both squamous carcinomas. Subsequent review of the clinical course of the patients supported the assessment of the gene classifier.²² In another study, a gene expression-based classifier was devised to distinguish metastases of head and neck squamous carcinoma from primary lung squamous cancer, a task made difficult by both the histo-

logic similarity as well as shared risks for both diseases. Ten genes were identified whose expressions enabled discrimination between tumors of the lung and of the upper aerodigestive origin with high accuracy in both the training and validation samples.²³ Certainly, molecular techniques provide new ways of classifying tumors and, in so doing, improve the ability to identify the origin of a lung nodule. When the prior tissue is available for comparison, molecular testing may also assist identification of the new nodule as either a metastasis or a new cancer.

Finding viral antigens may help identify malignancies and reveal different roles in pathogenesis. Recent recognition of the role of certain strains of *human papillomavirus* (HPV) in squamous carcinogenesis of the cervix and oropharyngeal mucosa had caused some investigators to investigate whether this oncogenic virus was involved in the development of lung squamous carcinoma.²⁴ However, in a recent study, investigators using both in situ hybridization and polymerase chain reaction based genotyping found that, in 132 squamous lung carcinomas, only 5 (1.5%) contained the HPV genome. All five of these patients had prior diagnoses of HPV-related squamous carcinoma in a different tissue and thus the HPV-positive tumors were considered to be metastatic.²⁵ This would suggest that the finding of HPV-associated squamous cancer in the lung might serve as an indicator of metastasis, particularly in the setting of a prior HPV-positive extrapulmonary malignancy.

OPTIONS FOR OBTAINING A TISSUE DIAGNOSIS

A diagnosis may be confidently made without the need for a biopsy when a patient with a history of prior cancer known to metastasize to the lungs presents with nodules with highly typical characteristics: multiple, new, or growing lower lobe pulmonary nodules with smooth borders. A diagnosis may also be possible without the need for a biopsy when, less commonly, there are measurable diagnostic serum markers (CA19-9, CA125, carcinoembryonic antigen, alpha-fetoprotein, β human chorionic gonadotropin, CYFRA21-1). However, for most tumors other than those of germ cell origin, these epithelial markers are not sufficiently specific and a biopsy is warranted to guide therapy. In all cases, before performing a lung biopsy, it is important to search for evidence of metastasis to other sites where a less invasive biopsy may yield the diagnosis. This should begin with a thorough physical examination directed to finding any enlarged lymph nodes, skeletal tenderness, or hepatomegaly that would guide the next imaging study or tissue sampling. In older series, much of the data on tissue biopsies is derived from surgical material, and this remains the “gold standard” due to the quantity of material available to the pathologist.¹⁷ Surgery is often used for diagnosis when it is the appropriate definitive therapy for patients with lung metastases from solid tumors. However, there are nonsurgical biopsy options, each with strengths and drawbacks that can be weighed to achieve the best balance between certainty, risk, and cost. Fiberoptic bronchoscopy, percutaneous CT-guided biopsy, and surgical resection are discussed herein, with each successive option providing increased accuracy (sensitivity and negative predictive value) but also increased risk and cost.

Bronchoscopy

Fiberoptic bronchoscopy is particularly useful for accessing centrally located lesions and mediastinal lymph nodes. Transbronchial needle aspiration of enlarged mediastinal lymph nodes is safe and has excellent diagnostic accuracy for malignant involvement of mediastinal lymph nodes. Use of *endobronchial ultrasound* (EBUS) improves sensitivity and permits the biopsy of much smaller lymph nodes in both the mediastinum and hilar lymph node stations (see Chapter 22). The accuracy of standard bronchoscopy for lung parenchymal lesions declines rapidly as the distance from the main-stem bronchi increases, so that traditional transbronchial sampling techniques have less than 20% sensitivity for peripheral lung nodules.²⁶ The increasing use and availability of navigational bronchoscopy has allowed biopsy of small peripheral lung nodules with significantly greater accuracy. Experienced users of this newer approach report a 69% to 80% sensitivity for the diagnosis of small peripheral lung nodules (as small as 7 mm, ranging up to 8 cm, and average size less than 2 cm).²⁷⁻²⁹ Combining navigation-assisted bronchoscopy with real-time imaging using a radial probe ultrasound catheter to confirm the location suggested by virtual images further increased the accuracy of transbronchial biopsy to 88% in one series.³⁰ Using bronchoscopy, multiple samples can be taken from one area or from multiple different nodules in a single procedure without an appreciable increase in the risk for pneumothorax. Given the low risk of pneumothorax (1% to 5%) and of major bleeding, the chief risk of the bronchoscopic biopsy, even when combined with electromagnetic navigation and real-time radial probe ultrasound, is that of a false-negative biopsy result.²⁹

CT-Guided Biopsy

CT-guided biopsy by experienced clinicians has excellent accuracy (see Chapter 19, Figs. 19-1 to 19-2).³¹ This approach has greater sensitivity than bronchoscopy, particularly for peripheral lesions. The sensitivity of CT-guided biopsy of lung nodules varies with the size of the lesion, with a 65% to 75% accuracy for smaller lesions (<1 cm diameter) and a greater than 95% sensitivity for lesions larger than 1.5 cm in diameter.³²⁻³⁴ Larger size and a more peripheral location are associated with greater diagnostic accuracy.³⁵ Core biopsies, in addition to or instead of cytologic material, can be obtained with larger 19-gauge needles (see Fig. 19-6). The major risk of CT-guided transthoracic needle biopsy is pneumothorax, which develops in up to 35% of patients and 10% to 15% requiring tube thoracostomy or catheter drainage.³⁶ The risk of pneumothorax appears to increase with the length of the needle tract, as well as the presence of obstructive lung disease.³⁵ In one large retrospective series, severe complications of CT-guided biopsy were quite rare. Of 9783 biopsies, 74 (0.75%) patients were reported to have severe complications, including 6 patients with air embolism (see eFig. 19-2), 10 with tension pneumothorax, 6 with severe pulmonary hemorrhage, 9 with hemothorax (see eFig. 19-1), and 6 with seeding of the needle tract. Eight deaths were reported.³⁶ In general, CT-guided biopsies are safe and accurate for peripheral lesions.

Surgery

Resection of a nodule provides the greatest diagnostic sensitivity and may provide both a diagnosis and treatment in a single procedure. The selection of patients for whom nodule resection is appropriate is a matter of controversy. There are few, if any, randomized studies comparing surgical and nonsurgical treatment of lung metastasis, and the data from reported series on surgical treatment of lung metastases suffer from a lack of uniformity in selection criteria. The sensitivity of surgery for diagnosis is likely close to 100% given that it is the accepted gold standard for tissue diagnosis of lung lesions. However, very small lung lesions can be difficult for the surgeon to palpate and may be missed. The risks of surgery include those for general anesthesia in addition to the risks associated with lung resection. Thoracoscopic surgery is discussed later and is the preferred option when surgery is required for diagnosis.

TREATMENT

MULTIMODALITY THERAPY OF POTENTIALLY CURABLE DISEASE

Treatment for lung metastasis is largely dictated by the tissue of origin (Fig. 55-3). In cases of curable cancers, patients with lung metastases should be treated aggressively with appropriate multimodal therapy. Germ cell tumors, neuroblastoma, gestational trophoblastic tumors, lymphoma, and osteosarcoma are included in this category. In certain cases, residual nodules persist following chemotherapy and can then be resected. In patients with nonseminomatous germ cell tumors, resection of residual nodules or masses after systemic chemotherapy is an aggressive but appropriate approach. In cases of testicular cancer, such residual masses after chemotherapy remain in approximately 40% of patients who had advanced disease but negative serum tumor markers at the conclusion of treatment.^{37,38} When resected, approximately half of these masses contain only necrotic tissue, a further 25% show a mature teratoma, and the rest contain residual carcinoma. Long-term follow-up studies after chemotherapy suggest that 90% of patients found to have mature teratoma on resection and 50% of those with residual carcinoma are cured by “adjuvant” surgery.^{37,38} In other tumors, treatment options are mainly nonsurgical. For patients with lymphoma, for example, in whom treatment alternatives are more numerous and systemic therapy is necessary, biopsy rather than excision is more appropriate. These varied treatment options highlight the importance of undertaking the care of these patients with multidisciplinary input.

PALLIATIVE CARE

Unfortunately, most adults with pulmonary metastases from solid tumors have incurable disease and palliative therapy is warranted. For selected cancers, palliative treatment may include radiotherapy, chemotherapy, or hormonal or biologic/targeted therapies. Agents chosen for

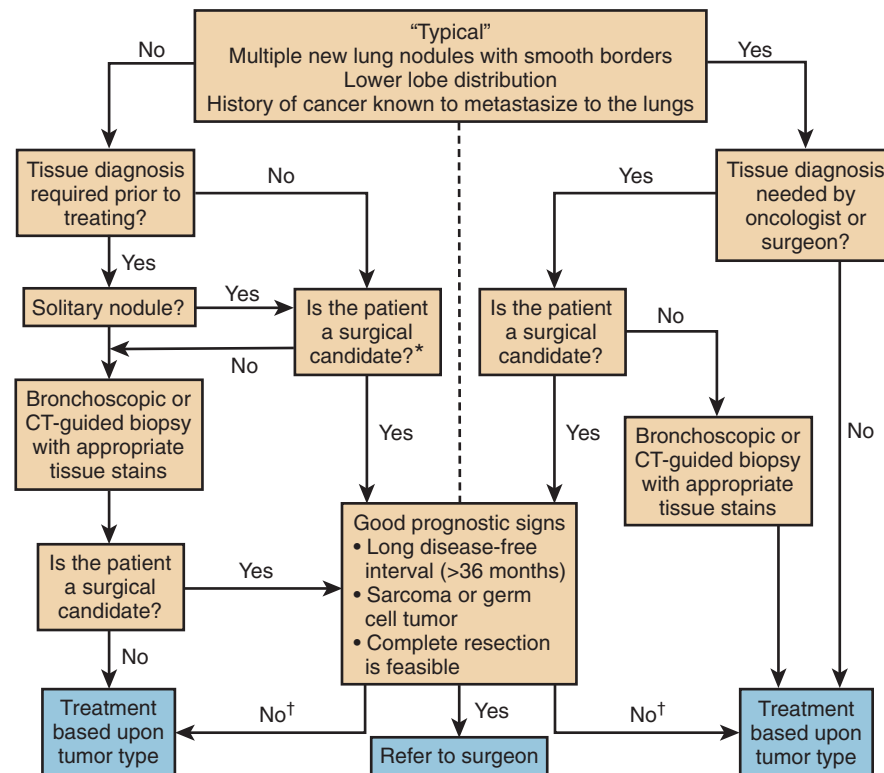

Figure 55-3 Suggested management algorithm for patients with known prior cancer and a new lung nodule. A suggested management algorithm taking into account the typical or atypical appearance of a lung nodule in a patient with prior known cancer, the utility of a tissue diagnosis to the treating physicians, the physiologic fitness of the patient for surgery, and the known prognostic indicators for a favorable outcome after metastasectomy. Each patient should be managed individually, within the context of the skills and experience of local providers with the varied diagnostic and therapeutic options. *Patients at high risk for primary lung cancer may be considered for diagnostic lobectomy, when appropriate. †These are suggested criteria for surgical resection of lung metastases, and multidisciplinary teams should make this decision. Radiofrequency ablation may be an excellent choice for these patients as well.

palliative therapy should balance acceptable levels of toxicity with the expected degree of tumor response and symptom control. Radiation therapy for patients with radiosensitive tumors can provide rapid and effective symptom relief. For patients with endobronchial obstruction, endobronchial tumor ablation using brachytherapy, laser, or cryoprobes can be very effective for palliation (see Chapter 23). Because these approaches require specialized training, it is best to seek referral to a center with experience in such techniques when they are needed. Because most centers may only specialize in one, or at most two, of these interventional methods, direct comparisons of the efficacy and safety of palliative interventions for malignant airway obstruction have not been reported. For patients with end-stage dyspnea, opiates, and oxygen therapy may relieve symptoms. In general, for end-of-life care, social, emotional, and physical rehabilitation support as well as hospice services are valuable.

RADIOFREQUENCY ABLATION OF METASTASES

Thermal ablation is a minimally invasive therapy that can be used for local cure or control of either primary or metastatic lung tumors. *Radiofrequency ablation* (RFA), which uses radiofrequency energy to generate frictional heating that leads to cell death, is the most commonly performed thermal ablation procedure used to treat lung tumors.

While the role of RFA is not as clearly defined as other options, studies supporting use of this procedure for lung metastases are mounting and the role for RFA in treating lung metastasis is gaining increased acceptance. Although RFA is more commonly performed to treat hepatic and renal tumors, it may be well suited to the lung due to its ability to concentrate thermal energy focally within tumor tissue with little or no energy spreading to the adjacent aerated normal lung parenchyma.³⁹

Smaller tumors, 3 cm or less in diameter, are more readily treated with RFA than larger tumors.^{40,41} Peripheral tumors surrounded by lung parenchyma and away from hilar structures can be safely treated with RFA (see Fig. 19-15).^{42,43} However, recent studies report that even tumors contiguous with certain vital structures, such as the thoracic aorta and pulmonary vessels, can be safely treated,⁴⁴ because the cooling effect of constant blood flow in large vessels may protect them from tissue damage. Multiple lesions in the same hemithorax can be treated at one sitting by experienced providers; however, because of the risk of pneumothorax (as high as 50% in one series⁴⁵), bilateral lesions should not be treated during the same procedure.

SURGICAL RESECTION OF METASTASES

As measured by length of survival and quality of life, surgical resection of pulmonary metastases can be the

Table 55-3 Suggested Criteria and Indications for Pulmonary Metastasectomy⁴⁸⁻⁵¹

ABSOLUTE CRITERIA
The patient must be able to tolerate the planned operative procedure
The primary tumor is controlled
No extrapulmonary metastases exist; or, if present, they must be controllable
Pulmonary metastases are completely resectable
RELATIVE INDICATIONS
Pulmonary metastases are symptomatic (e.g., pneumothorax, hemoptysis)
Surgery is necessary to differentiate metastasis from primary lung cancer

appropriate choice. As resection has become more common, factors associated with good outcome have been identified from registries of patients treated with surgery. In general, the most important factor associated with improved survival is the complete resection of all metastases. Incomplete resection is associated with dismal survival rates that do not differ from those with no treatment at all. Another important favorable prognostic factor in numerous large series is a long disease-free interval between initial diagnosis of cancer and the discovery of lung metastasis.⁴⁶⁻⁴⁸ Five-year survival was 33% when the disease-free interval was 0 to 11 months compared with 45% when the disease-free interval was more than 36 months.^{49,50} Although once considered a poor prognostic factor, a higher number of pulmonary metastases has not been consistently shown to be a negative predictive factor. More accurate prognostic factors must be identified to improve selection of patients for metastasectomy. Suggested selection criteria for pulmonary metastasectomy, taken from various large series,^{48,51} are shown in Table 55-3. In a retrospective analysis, selection of patients for pulmonary metastasectomy according to these criteria was associated with longer survival times.⁴⁸

In 1991, the International Registry of Lung Metastases (comprised of more than 5000 cases) was established to record and report upon the long-term results of pulmonary metastasectomy for various primary malignancies.⁵¹ According to the registry, long-term success of pulmonary metastasectomy varies according to the primary malignancy. Cancers that metastasize exclusively to the lungs have more favorable outcomes from pulmonary metastasectomy than cancers that metastasize more widely. Malignancies with the greatest long-term survival after pulmonary metastasectomy include osteogenic and soft tissue sarcoma, colorectal cancer, uterine/cervical tumors, head and neck cancer, breast cancer, testicular tumors, renal cell tumors, and melanoma (Table 55-4). Patients undergoing lung metastasectomy for osteosarcoma have some of the best results, but long-term survival after metastasectomy is not limited to patients with sarcoma.⁵¹ Prolonged disease-free survival has been reported for patients with colon cancer, breast cancer, prostate cancer, and other malignancies. Pulmonary metastasectomy for any cancer mandates adherence to certain surgical principles: complete resection is possible, the primary tumor is controlled, and there are no other uncontrolled extrapulmonary metastasis.

Table 55-4 Tumor-Specific 5-Year Survival Rates Following Pulmonary Metastasectomy

Primary Malignancy	5-Year Survival (%)
Soft tissue sarcoma ⁶³⁻⁶⁵	20-35
Osteosarcoma ⁶⁶	25-50
Melanoma ^{67,68}	5-33
Colorectal ^{69,70}	13-40
Testis (germ cell) ^{37,71}	50-80
Renal ^{72,73}	15-20
Breast ^{47,74,75}	25-50
Head and neck ⁷⁶	30

Surgical resection of pulmonary metastases requires careful planning and preparation. As with any lung resection, the number, location, and size of the lesion, pulmonary function, and the general condition of the patient must be considered, as must any evidence for local invasion, or the prospects for response to systemic therapy. CT has the greatest sensitivity and accuracy for localizing pulmonary nodules for resection. Small nodules can be localized using image-guided wires, dyes, and coils, as well as ultrasound and radiation probes. An emerging strategy is to mark small peripheral tumors before thoracoscopic resection using wire, dye, radioactive tracer, or coils (see Fig. 19-17).⁵² These markers can be placed either percutaneously or bronchoscopically (typically using navigational bronchoscopy) before resection. Intraoperative localization of small nonpalpable nodules can be aided with a sterile ultrasound or radioactivity probe in deflated lung.

In tumors that can be detected with PET scanning, the scanning should be performed before pulmonary metastasectomy to exclude the presence of synchronous extrapulmonary metastasis that would negate the benefit of lung resection. Uptake on PET or lymph node enlargement seen on CT can suggest less invasive biopsy techniques such as mediastinoscopy, transthoracic needle biopsy, and transbronchial needle biopsy (with or without endobronchial ultrasound). With the exception of certain germ cell tumors (which may remain curable despite metastatic disease), finding synchronous metastasis outside the lung would be a contraindication to pulmonary metastasectomy.

Thoracotomy has been the most frequently used approach for unilateral metastasectomy, primarily because it enables the surgeon to palpate the lung for lesions. Similarly, sternotomy has been used for bilateral palpation and metastasectomy. To avoid the morbidity of a thoracotomy or sternotomy, alternate surgical approaches have been sought. Subxiphoid pulmonary metastasectomy has been described.⁵³ The subxiphoid approach permits palpation of both lungs without transecting large muscles or bone. Thoracoscopy also allows minimally invasive resection of pulmonary metastases, but thoracoscopic pulmonary metastasectomy has been criticized based upon its limited ability to permit palpation of the lungs to identify unknown metastases. However, as the resolution of CT scanning improves, the likelihood of pulmonary nodules that can be palpated but not visualized on CT scan decreases dramatically, thus improving the relative utility of a thoracoscopic

approach for metastasectomy. In addition, instruments and techniques have evolved to allow enhanced visualization and even thoroscopic palpation of lung parenchyma. Compared to thoracotomy, thoroscopic metastasectomy has several advantages including smaller incisions, less pain, earlier recovery, and fewer postoperative adhesions. The latter is especially important in that repeat pulmonary metastasectomy may be indicated based on the same criteria as the initial metastasectomy.^{50,51} Indeed, recurrence develops in more than 50% of patients who undergo complete pulmonary metastasectomy. The probability of relapse is higher for sarcoma and melanoma than for epithelial or germ cell tumors. In the international registry, repeat metastasectomy yielded 44% survival at 5 years and 29% at 10 years,⁵¹ which is comparable to the results after initial metastasectomy. A retrospective nonrandomized study comparing outcomes of patients who had undergone metastasectomy with open versus thoroscopic approaches did not find differences in survival, although complications and hospital length of stay were predictably less after a thoroscopic approach in this nonrandomized comparison.⁵⁴ Thus, the approach for surgical resection should be carefully planned with respect to several criteria, including the number and location of lesions, the surgeon's experience, and the possible need for repeat metastasectomy.

Before any resection, all lung lesions should be identified in order to plan a resection that minimizes the loss of lung parenchyma. The extent of pulmonary resection is an important consideration. Of those undergoing surgical resection of metastatic disease, metastasectomy was achieved by wedge resections in 67%, segmentectomy in 9%, and lobectomy or bilobectomy in 21%.⁵¹ Lymph node dissection is not encouraged due to the low incidence of nodal involvement with pulmonary metastasis, associated morbidity, and the poor survival of patients with nodal metastasis regardless of resection. Pneumonectomy or extended resection was rarely used (3%) and should be reserved for special circumstances when there is acceptable surgical risk and a reasonable likelihood of long-term survival.⁵¹

The morbidity and mortality for pulmonary metastasectomy should be very low. Most series report less than 2% mortality and 10% morbidity.⁵¹ The most common complications are persistent air leak and infection. Preoperative chemotherapy or radiation may increase the risk of respiratory failure after metastasectomy when high fractional concentrations of oxygen are used perioperatively.³⁸ Anesthesiologists should be alerted to a history of chest irradiation or chemotherapy (particularly with bleomycin used for germ cell tumors) and use the lowest possible fractions of inspired oxygen for these patients. With appropriate patient selection, the survival following pulmonary metastasectomy can be quite good. The decision to operate should be influenced less by the type of prior cancer than on the eligibility criteria described in [Table 55-3](#).

Most reports regarding the effectiveness of pulmonary metastasectomy have been retrospective. These nonrandomized and uncontrolled series introduce selection and lead-time bias, which must be kept in mind when considering treatment options. Reported survival rates of 30% to 40% at 5 years is encouraging, but the selection criteria used for surgical resection, as well as the nonrandomized

nature of these studies, must be taken into consideration. Additional studies are needed to define candidates that will receive maximum benefit from pulmonary metastasectomy. For example, molecular predictors of prognosis have been used to assess treatment options for primary tumors, but this has been more difficult to incorporate into an algorithm for treating metastases because of the diversity of origins of primary tumors and relatively small numbers reported in any given series of metastasectomy.⁵⁵

SPECIAL CASES

AIRWAY METASTASIS

While rare, large airway involvement with endobronchial metastasis can produce very distressing symptoms of dyspnea and/or hemoptysis. Awareness of the clinical scenario along with available diagnostic and management strategies can be very helpful in palliating these patients. Reported series of patients with endobronchial metastasis are generally small but uniformly emphasize the utility of fiberoptic bronchoscopy for diagnosis, as well as interventional methods for symptom control and palliation. Other than lung cancer, many tumors metastasize to the bronchi, including colon, breast, renal cell carcinoma ([eFig. 55-1](#)), and melanoma.⁵⁶⁻⁵⁸ Breast and colon cancers predominate in reported case series of endobronchial metastases, perhaps because they are more prevalent in the general population of cancer patients. It should be noted that colon cancer can metastasize to the bronchi without involvement of the liver.⁵⁷ Radiation can be used for palliation in patients with malignant airway obstruction and radiosensitive tumors. Mechanical means, including stents and endobronchial ablative methods (laser, cryoprobe, argon plasma coagulation, or physical débridement) can be used for tumors that are relatively radioresistant (see [Chapter 23](#)).

VASCULAR EMBOLIC METASTASIS

A rare but dramatic presentation of lung metastasis is tumor embolism. When clinically evident, the symptoms are those of "subacute cor pulmonale" with dyspnea, edema, elevated jugular venous pressure, and auscultatory evidence of pulmonary hypertension and right ventricular failure. Premortem diagnosis is difficult unless clinical suspicion is high. Tumor emboli have been reported as the initial presentation of extrapulmonary cancer or as a postmortem finding in those with no premortem respiratory symptoms.⁵⁹ In a series of 214 selected autopsies, 89 patients had evidence of tumor emboli, and only 50 of these had clinical records indicating the presence of respiratory symptoms before death. However, in 29 of the 50, tumor emboli were the recorded cause of death.⁶⁰ Tumors arising from the breast, liver, and pancreas accounted for more than 50% of the cases, but many tumor types were represented among this series.⁵⁹ Pulmonary arterial tumor emboli may affect larger pulmonary arteries, so-called macroscopic tumor embolization, which may be visible on chest CT ([eFigs. 55-2](#) and [55-3](#)). Small pulmonary arteries may also be affected by tumor embolization, a situation often referred to as "microscopic tumor embolization" ([eFig.](#)

55-4). Chest CT findings of this condition (see eFig. 55-4A-C) include small centrilobular opacities, possibly with branching configurations (simulating infection), smooth or nodular interlobular septal thickening, and areas of ground-glass opacity or parenchymal consolidation, reflecting hemorrhage or infarction. When tumor embolism is suspected, cytologic examination of pulmonary capillary blood obtained via a wedged pulmonary arterial catheter is a possible diagnostic method.⁶¹

PLEURAL METASTASES (see Chapter 82)

Malignant pleural effusions are always metastatic and are a significant cause of morbidity in patients with cancer. Diagnosis is typically straightforward and can be made in pleural fluid with cytology, although this may require more than one thoracentesis if initial cytology is negative. Flexible thoracoscopic examination of the pleural space is increasingly used to diagnose pleural metastasis. A recent randomized study demonstrated the superiority of indwelling tunneled pleural catheters using outcome measures of long term symptom relief and initial hospital length of stay when compared with talc pleurodesis. However, there was no difference in validated quality of life metrics between the two groups, and blockage of the indwelling catheter was a common complication of the group treated with this approach.⁶²

Key Points

- Lung metastases are common and arise from most types of solid tumors.
- In addition to benign causes, a pulmonary nodule in a patient with prior cancer can be a metastasis or a primary lung cancer; the likelihood of metastasis will vary with the original type of cancer and lung cancer risk factors.
- When clinical and/or histologic evaluation cannot distinguish primary lung cancer from metastasis, immunohistochemistry for tumor-specific markers

can be useful. Future directions will include molecular phenotyping.

- The choice of diagnostic method will be determined by the patient's status, the natural history of the prior cancer, the availability of specialized diagnostic methods and the need, or lack thereof, for a tissue diagnosis before offering therapy.
- Radiofrequency thermal ablation is a potential therapeutic option when surgical resection, radiation, or systemic therapy is not.
- Surgery for both diagnosis and treatment is appropriate for selected patients. The most important predictor of successful treatment is the ability to achieve complete metastasectomy of all visible and palpable lung nodules.

Intrapulmonary Meningioma**MISCELLANEOUS****SUMMARY****INTRODUCTION**

Although in practice the terms “tumor” and “neoplasm” tend to be used interchangeably, there is an important and substantial difference between them. A “tumor” need not be a neoplasm (e.g., a granuloma forms a “tumor”), and “neoplasms” do not always form tumors (e.g., lymphangitic carcinoma or leukemia). Entities discussed in this chapter are all benign neoplasms (generally distinguished from malignant neoplasms by their lack of invasion or metastasis) that form tumors. In general, these benign entities are uncommon, accounting for fewer than 5% of resected lung neoplasms. While many are rare, some benign lung tumors are seen with sufficient frequency to pose periodic diagnostic challenges for primary care providers, pulmonologists, radiologists, surgeons, and pathologists alike. In this chapter, we briefly review the clinical and pathologic features of benign lung neoplasms. Nonneoplastic conditions that may mimic tumors on imaging studies (e.g., granulomas, organizing pneumonia) or certain low-grade but fully malignant neoplasms, such as carcinoid tumors, are not discussed.

CLINICAL MANIFESTATIONS

Most benign lung tumors present as asymptomatic solitary pulmonary nodules typically discovered on chest radiographs or *computed tomography* (CT) scans performed for other purposes. A minority cause symptoms due to airway obstruction, bleeding, or compression of other structures. A preoperative diagnosis may be possible based on a combination of imaging studies and either endoscopic or percutaneous needle biopsies, but most are recognized only after surgical resection of a lesion in which the possibility of malignancy could not be categorically excluded.^{1,2}

A decision to proceed with surgical resection in a patient with an unexplained solitary pulmonary nodule is complex and predicated on analysis of various risk factors. Currently recommended approaches include watchful waiting in selected patients.³⁻⁷ Prediction models for the likelihood of malignancy⁸⁻¹² and Fleischner guidelines for the management of indeterminate pulmonary nodules^{11,12} are very useful in suggesting watchful waiting for nodules at low risk (<10% probability of malignancy). The approach to the solitary pulmonary nodule is also discussed in Chapter 53.

It is worth noting that many benign lung tumors are discovered as solitary pulmonary nodules. As such, individuals with these entities are often evaluated by ¹⁸F-fluorodeoxyglucose positron emission tomography (PET) scans. Contrary to what one might expect, ¹⁸F-fluorodeoxyglucose (FDG) uptake is quite common among benign lung tumors, and the PET scan cannot therefore reliably discriminate benign from malignant lung tumors.

BENIGN EPITHELIAL TUMORS**PAPILLOMAS AND ADENOMAS****Solitary Papillomas**

Papilloma refers to exophytic endobronchial lesions with a papillary architecture (Fig. 56-1). Most solitary papillomas arise in central large airways (see eFig. 56-1); rarely, they arise in smaller bronchioles and present as peripheral nodules.¹³ Flieder and associates divided lung papillomas into three categories based on the lining epithelium: squamous cell, glandular, and mixed types.¹⁴ Squamous lesions account for nearly 70% of reported cases and are seen more frequently in men, and are more often associated with cigarette smoking and *human papillomavirus* (HPV) infection. Associated foci of squamous cell carcinoma in situ are rare, with only a single well-documented example of invasive carcinoma developing in a patient without respiratory papillomatosis (see later).¹⁵ Most patients with papillomas do well regardless of histologic type. Surgical resection is curative. Local recurrences are rare and limited to patients whose papilloma is not completely resected either because they undergo only biopsy or receive a subtotal bronchoscopic removal. The differential diagnosis includes rare endobronchial papillary variants of squamous cell or adenocarcinoma, a distinction that depends on recognition of cytologic atypia and stromal invasion.

Recurrent respiratory papillomatosis (RRP), also termed juvenile laryngeal or laryngotracheal papillomatosis, is a form of HPV-mediated papillomatosis that presents in early childhood.¹⁶ Presenting symptoms include hoarseness, change or loss of voice, cough, and respiratory distress or stridor. HPV types 11 and 6 have been most commonly implicated and are perinatally acquired from mothers with genital infection.¹⁶ Surgical excision or laser ablation are

Figure 56-1 Papillomas. Low-magnification photomicrographs illustrate two different solitary endobronchial papillomas from adults. **A**, Squamous papilloma showing papillary architecture with central connective tissue stalk covered by benign squamous epithelium with associated keratinous debris. (H&E stain; original magnification $\times 20$.) **B**, Glandular papilloma lined by benign mucinous columnar cells with abundant extracellular mucus. (H&E stain; original magnification $\times 40$.)

the mainstays of therapy for patients with symptomatic disease.¹⁶ Recurrences are the rule and often necessitate multiple procedures. Squamous cell carcinoma is an infrequent complication but can affect either the upper or lower respiratory tracts.¹⁷⁻¹⁹

The lung parenchyma is involved in about 3% of patients with juvenile onset RRP.^{20,21} HPV-11 is especially prevalent in patients in whom peripheral lung disease develops, accounting for nearly 90% in whom testing was performed.²⁰ The latent period between diagnosis of RRP and recognition of lung involvement is variable, usually 8 to 10 years.²⁰ Parenchymal disease presents as multiple asymptomatic nodules that may be cystic or solid (Figs. 56-2 and 56-3; see eFigs. 54-29 through 54-31).²⁰⁻²² Symptomatic patients present with cough and various combinations of hemoptysis, dyspnea, fever, and chest pain. Case reports describing significant uptake of FDG in PET scans suggest that lesions of RRP can be very FDG-avid.¹⁹ The histopathologic findings are unique, demonstrating tufts of benign squamous papillomas emanating from distal bronchioles with polypoid extensions into adjacent alveolar spaces (Fig. 56-4). The involved bronchioles are often ectatic, thus mimicking the appearance of cavitation on imaging studies.

Figure 56-2 Recurrent respiratory papillomatosis. CT of a patient with recurrent respiratory papillomatosis involving her right lung. There are multiple nodules and opacities, the largest measuring 3 cm in greatest dimension. Some of the nodules appear cavitated. (Courtesy Dr. Jay Ryu, Professor of Medicine, Mayo Medical School.)

Figure 56-3 Recurrent respiratory papillomatosis. Gross photograph of excised left lower lobe from a 19-year-old with multiple recurrences of respiratory papillomatosis as described by Kerley and coworkers.²² The patient had extensive papillomatosis involving his central airways and a large cystic cavity containing innumerable papillomas replacing much of his left lower lobe.

Parenchymal lung involvement in patients with RRP is often associated with an aggressive course. There is currently no effective medical therapy. Interferon and cidofovir, an antiviral agent, show inconsistent results; in addition, cidofovir has been implicated as potentially oncogenic.²⁰ About 15% of patients with parenchymal disease develop squamous cell carcinoma of the lung, with an average age at carcinoma diagnosis of 23 years (see eFig. 54-32).²⁰ No risk factors clearly identify those patients likely to develop lung carcinoma. Nearly two thirds of reported patients have died of disease, many of squamous cell carcinoma.²¹

Adenomas

Historically the term *adenoma* was applied to a pathologically heterogeneous group of low-grade endobronchial malignancies that included carcinoid tumors and carcinomas homologous to those arising from salivary glands (i.e., adenoid cystic and mucoepidermoid carcinomas).²³⁻²⁵

Figure 56-4 Recurrent respiratory papillomatosis. Photomicrographs illustrate lung involvement in a 40-year-old woman first diagnosed with recurrent respiratory papillomatosis at the age of 2 years. She underwent multiple resections of lung nodules starting in her second decade of life. **A**, Low-magnification photomicrograph illustrates multiple benign papillomas within an ectatic bronchiole with a centrally dilated lumen. (H&E stain; original magnification $\times 20$.) **B**, High-magnification photomicrograph illustrates cytologically bland, benign appearance of the lung papillomas. (H&E stain; original magnification $\times 400$.)

Today the term is restricted to a group of benign neoplasms with variable clinical presentations and histologic appearances.

Endobronchial adenomas include two entities analogous to salivary gland counterparts. *Mucous gland adenomas* are rare, presenting as potentially obstructing, sessile, endobronchial masses arising at the level of lobar or segmental bronchi.²⁶⁻²⁸ Average age at diagnosis is 52 to 54 years but with a broad age range that extends to childhood. Most patients are symptomatic at the time of diagnosis. The most frequent complaints are cough, shortness of breath, and wheezing, a combination of findings that can be misconstrued as asthma.²⁸ Some patients are symptomatic for years before the diagnosis is made. Chest radiographs may be normal but more commonly show a solitary pulmonary nodule and/or postobstructive atelectasis or consolidation.²⁷ CT scans show discrete nodules that may be accompanied by an air-meniscus sign attesting to an endobronchial location.²⁷ Histologically, mucous gland adenomas are variably solid and cystic, and composed of cytologically bland columnar mucinous cells (Fig. 56-5). Surgical resection, which is often required for diagnosis, is curative.

Figure 56-5 Endobronchial mucous gland adenoma. This low magnification photomicrograph shows that the smooth surface is covered by ciliated respiratory epithelium whereas the core comprises predominantly cystic spaces lined by variably attenuated columnar mucinous cells. (H&E stain; original magnification $\times 20$.)

Pleomorphic adenomas, also termed benign mixed tumors, are biphasic neoplasms composed of stromal and epithelial elements. They usually arise in major salivary glands; there are fewer than 20 well documented examples of primary lung tumors.²⁹⁻⁴⁰ Primary pulmonary pleomorphic adenomas have been reported more commonly in women than men (ratio 2:1), with an average age at diagnosis of about 51 years. Cough is the most frequent presenting complaint and is sometimes associated with postobstructive pneumonia. One third of patients are asymptomatic when a solitary pulmonary nodule is discovered. Eighty percent are found within the larger central airways as polypoid exophytic tumors. Chest radiographs and CT scans show a solitary well-circumscribed solid mass without distinctive features. PET in a single patient showed high FDG avidity.³³ Complete surgical resection with tumor-free margins is curative. As can happen with their salivary gland counterparts, benign pleomorphic adenomas can undergo transformation to malignant carcinoma (*carcinoma ex pleomorphic adenoma*).³⁴ Primary pleomorphic adenoma must be distinguished from so-called benign metastasizing pleomorphic adenoma, a term that refers to rare patients in whom histologically benign salivary gland tumors inexplicably metastasize to various sites, including lung.^{41,42}

Adenomas involving peripheral lung parenchyma are rare. *Alveolar adenoma* is the most common variant with just under 30 reported examples.⁴³⁻⁴⁷ Average age at diagnosis is between 50 and 55 years. Nearly all patients are asymptomatic at the time of diagnosis. Radiologically, alveolar adenomas present as well circumscribed peripheral nodules averaging just over 2 cm in greatest dimension. Magnetic resonance imaging may show a cystic space with central fluid and thin-rim enhancement.⁴⁴ Pathologically, alveolar adenomas are partially cystic nodules in which connective tissue septa are lined by cytologically bland epithelial cells (Fig. 56-6). The epithelial cells are derived from pneumocytes while the stromal cells are undifferentiated fibroblasts. Cytogenetic studies performed in a single case demonstrated a clonal translocation supporting the conclusion that these are indeed neoplasms, although their behavior is benign.⁴⁸

Figure 56-6 Alveolar adenoma. **A**, Low-magnification photomicrograph shows a well-demarcated partially cystic mass in a peripheral lung biopsy. (H&E stain; original magnification $\times 20$.) **B**, Higher-magnification photomicrograph illustrates connective tissue septa lined by bland pneumocytes. (H&E stain; original magnification $\times 400$.)

Papillary adenomas have been described in fewer than 10 patients.⁴⁹⁻⁵² All patients in whom the lesion was discovered during life underwent surgical resection for an asymptomatic solitary peripheral nodule and remained free of disease at follow-up. Histologically, papillary adenomas are circumscribed lesions composed of connective tissue fronds lined by bland type 2 pneumocytes (Fig. 56-7).

Mucinous cystadenoma is a rare lung neoplasm that overlaps with unequivocally malignant mucinous adenocarcinomas.⁵³⁻⁵⁸ Gao and Urbanski proposed separating them into three histologically defined categories: mucinous cystadenoma, mucinous cystic tumor with atypia, and mucinous cystadenocarcinoma.⁵⁴ Histologically, benign tumors without atypia accounted for only 13% of reported patients, further emphasizing that this is an extremely rare neoplasm. Patients typically present with slowly growing, well-demarcated, peripheral lung masses that may or may not appear cystic.⁵⁶⁻⁵⁹ All patients with histologically benign cystadenomas have remained free of disease after surgical resection.

MICRONODULAR PNEUMOCYTE HYPERPLASIA

Micronodular pneumocyte hyperplasia is an unusual proliferation of alveolar epithelium seen almost exclusively in

Figure 56-7 Papillary adenoma. High-magnification photomicrograph of a solitary peripheral lung nodule shows papillary connective tissue cores lined by bland cuboidal pneumocytes. (H&E stain; original magnification $\times 400$.)

Figure 56-8 Micronodular pneumocyte hyperplasia (MNPH) in tuberous sclerosis complex (TSC) without lymphangioleiomyomatosis. **A**, CT of a 41-year-old woman with TSC and MNPH shows multiple bilateral nodules characterized by ground-glass attenuation. **B**, Photograph of autopsy lung specimen from another patient with TSC and MNPH (arrows). (**A**, courtesy Dr. Jay Ryu, Professor of Medicine, Mayo Medical School.)

patients with underlying tuberous sclerosis complex and/or lymphangioleiomyomatosis.⁶⁰⁻⁶⁴ More than 85% of reported patients were women. Radiologic findings are characterized by scattered nodules that are occasionally numerous and distributed in a miliary fashion, with or without the associated cystic changes typical of lymphangioleiomyomatosis (see eFig. 56-2).^{61,63} The radiologic abnormalities correspond to ill-defined pale peripheral nodules that are seen either in isolation or in the setting of lymphangioleiomyomatosis (Figs. 56-8 and 56-9). Histologically, micronodular

Figure 56-9 Micronodular pneumocyte hyperplasia (MNPH) associated with lymphangioleiomyomatosis (LAM). **A**, CT scan of a 55-year-old woman with tuberous sclerosis complex and LAM and a right lung nodule (arrow) attributed to MNPH. **B**, Photograph of a surgical lung specimen shows a combination of LAM and MNPH (arrows). (A, courtesy Dr. Jay Ryu, Professor of Medicine, Mayo Medical School.)

pneumocyte hyperplasia demonstrates circumscribed proliferations of bland pneumocytes cytologically identical to those seen in papillary adenomas, differing in that they are distributed along intact alveolar septa rather than along papillae (Fig. 56-10).

SCLEROSING HEMANGIOMA

Sclerosing hemangiomas (SH) are benign lung neoplasms derived from incompletely differentiated respiratory epithelium. The term *hemangioma* is a misnomer based on pseudovascular blood-filled spaces seen in some cases. SH presents with a female-to-male predominance of 7:1.⁶⁵⁻⁷³ Mean age at diagnosis is the fifth decade of life, although they have been reported in a wide age range including children. More than three fourths of patients are asymptomatic at the time they are discovered to have a solitary pulmonary nodule. CT scans show a well-circumscribed round or oval subpleural nodule with smooth margins and inhomogeneous enhancement (see eFig. 56-3).^{74,75} Associated calcifications are present in about one third of patients. Dynamic contrast CT studies show strong, rapid enhancement that rivals the imaging characteristic of malignancies.⁷⁶ PET scanning has been reported in only one patient and was

Figure 56-10 Micronodular pneumocyte hyperplasia. Histologic features are shown from the tuberous sclerosis complex patient also illustrated in Figure 56-8B. **A**, Low-magnification photomicrograph shows a well-circumscribed nodule. (H&E stain; original magnification $\times 20$.) **B**, High-magnification photomicrograph shows cytologically bland pneumocytes distributed along alveolar septa. (H&E stain; original magnification $\times 400$.)

characterized by intermediate FDG avidity.⁷⁷ Multiple lesions are seen in about 2% of patients. Deposits in regional lymph nodes are rare and have no impact on the fundamentally benign behavior of these lesions.⁷⁸⁻⁸⁰

Resected SH are well circumscribed subpleural nodules averaging 2 to 3 cm in diameter (Fig. 56-11). The histologic hallmark is a heterogeneous appearance resulting from both a mixture of cell types and highly variable growth patterns. Two populations of epithelial cells are a characteristic feature: (1) surface cuboidal cells derived from pneumocytes or club cell (Clara), and (2) pale interstitial round cells with an incompletely differentiated respiratory epithelial phenotype.^{69,81-83} Molecular studies using a variety of techniques suggest that both populations of cells are neoplastic, an observation that fits with descriptions of both components in nodal deposits.^{79,84,85} The cells are arranged in various growth patterns that include a focally conspicuous sclerotic stroma that is often calcified (Fig. 56-12).

Recent molecular studies of SH have demonstrated alterations at *P16* and *RB* that resemble those found in early stage adenocarcinomas, supporting an origin from

Figure 56-11 Photograph of resected sclerosing hemangioma. The lobulated nodule is well circumscribed and situated near the visceral pleura. The cut surface betrays the fundamentally heterogeneous nature of these neoplasms, showing a variegated pattern of pale brown and white with both solid and spongy areas.

Figure 56-13 Pulmonary hamartoma. CT of a proven hamartoma shows a well-margined nodule in which there is evidence of intratumoral fat and calcification. This combination is characteristic but is seen in only about a fourth of cases.

Figure 56-12 Sclerosing hemangioma. **A**, Low-magnification photomicrograph shows the classic features of sclerosing hemangioma in which sclerotic zones with dense collagen deposition and focal calcifications (arrows) alternate with variably cellular regions. (H&E stain; original magnification $\times 2$.) **B**, Higher-magnification photomicrograph shows solid and papillary growth patterns. The central area is solid and composed of the pale-staining round cells demonstrating a phenotype consistent with incompletely differentiated respiratory epithelium. (H&E stain; original magnification $\times 400$.)

respiratory epithelial cells and suggesting similarities between the molecular pathogenesis of SH and lung carcinoma.⁸⁶ However, a more recent molecular analysis of SH failed to identify alterations in some genes (*EGFR*, *HER2*, and *KRAS*) that are commonly mutated in adenocarcinoma, thereby raising doubts about a common link.⁸⁵ Genome-wide approaches will likely be necessary to resolve this controversy.

BENIGN NONEPITHELIAL LESIONS

HAMARTOMA AND RELATED LESIONS

Pulmonary hamartomas are the most common benign neoplasm in adults who undergo surgical resection. They are present in less than 0.5% of consecutively autopsied patients.^{2,87,88} Although the term *hamartoma* implies that these are tumor-like malformations rather than true neoplasms, recent studies show consistent and characteristic genetic abnormalities indicating that hamartomas are clonal neoplasms.

Pulmonary hamartomas are discovered in men more often than in women by a ratio of 2:1 with an average age at diagnosis in the sixth or seventh decade of life.^{89,90} Most patients present with asymptomatic solitary lung nodules with no lobar predilection. Multiple nodules are present in 2% or less of patients.^{89,91} Endobronchial hamartomas (see eFig. 56-4 and Video 56-1), more likely to be associated with cough, are seen in about 10% of patients. CT scans show a characteristic combination of calcifications and/or fat in two thirds of patients (Fig. 56-13; see eFigs. 54-23 through 54-27).⁹² Resection is nearly always curative with rare reports of recurrence or malignant transformation.^{93,94}

Pulmonary hamartomas usually manifest as well-circumscribed nodules, averaging 1.5 to 2 cm in diameter. A variegated cut surface reflects an admixture of stromal elements (Fig. 56-14). Mature hyaline cartilage is an almost universal component and is typically intermingled with

Figure 56-14 Photograph of resected hamartoma. The cut surface of this well-circumscribed nodule shows glistening irregularly shaped cartilaginous islands alternating with pale yellow adipose tissue. The tumor was 4 cm in greatest dimension.

mature fat, fibromyxoid tissue, and rare smooth muscle cells (Fig. 56-15). Any of the stromal components can predominate, however, resulting in a histologic spectrum of neoplasms that includes *leiomyomas* and *lipomas*.⁹⁵⁻⁹⁷ Entrapped nonneoplastic respiratory epithelium often results in a characteristically biphasic appearance, a phenomenon that contributes to relatively high rates of false-positive diagnoses of carcinoma in fine-needle aspiration biopsies (the most common false-positive diagnoses being carcinoid, adenocarcinoma, and small cell carcinoma).⁹⁸

Pulmonary hamartomas, like other benign mesenchymal tumors such as lipoma and leiomyomas, frequently contain chromosomal rearrangements of genes encoding nonhistone chromosomal high-mobility group family of proteins (HMG family) with AT-hook DNA-binding motifs.⁹⁹⁻¹⁰² These proteins play a broad role in growth, differentiation, proliferation, and death of mesenchymal cells through a mechanism that involves regulation of transcription via modification of DNA conformation.¹⁰³ Two main cytogenetic regions containing abnormalities have been defined in pulmonary hamartoma: 6p21 and 12q14-15. The *HMGA1* (also known as *HMG1Y*) gene maps to 6p21.3, whereas *HMGA2* (also known as *HMGIC*) maps to 12q14-15. Their dual role as regulators of mesenchymal differentiation and of gene expression is provocative, although additional work needs to be done to fully elucidate the role of *HMGA* fusion genes in pulmonary hamartoma.

Pulmonary chondroma, a related cartilaginous lung tumor, constitutes one component of the triad (i.e., pulmonary chondroma, paraganglioma, gastric stromal tumors) described by Carney in 1977.¹⁰⁴ Pulmonary chondromas develop in about three fourths of patients with Carney syndrome and are multiple in half of these.^{91,105} Chondromas are distinct in being purely cartilaginous without the other stromal and epithelial elements characteristic of hamartoma.⁹¹

Figure 56-15 Pulmonary hamartoma. Low-magnification photograph of a typical pulmonary hamartoma in which cartilaginous islands are interspersed with adipose tissue resulting in a lobulated appearance. (H&E stain; original magnification $\times 20$.)

INFLAMMATORY MYOFIBROBLASTIC TUMOR

Inflammatory myofibroblastic tumors (IMTs) of the lung comprise a spectrum of lesions ranging from benign spindle cell tumors to frankly malignant sarcomas. Pulmonary IMTs, also termed *plasma cell granulomas* by Bahadori and Liebow,¹⁰⁶ are defined in the WHO classification of lung tumors as “a subgroup of the broad category of ‘inflammatory pseudotumours.’”¹⁰⁷ The staggering profusion of synonyms that have been applied to these unusual tumors, which also is seen in multiple extrapulmonary sites, reflects the controversy and confusion regarding their pathogenesis and histogenesis.

IMTs of the lung can arise in any age group but tend to affect children and young adults; more than half of patients are younger than 40 years of age at the time of diagnosis.¹⁰⁶⁻¹¹³ Most patients present with asymptomatic peripheral lung nodules. Endobronchial tumors (see eFig. 56-5) account for around 15% of patients and may be accompanied by symptoms of cough and/or hemoptysis. Chest imaging studies typically show a well-circumscribed mass ranging in size from 0.8 cm to more than 30 cm (Fig. 56-16, see eFigs. 54-19 and 54-20 and eFig. 56-6), with the majority measuring between 1 and 6 cm in greatest dimension.^{106,110,112,114-116} Most primary pulmonary IMTs are cured with complete surgical resection.^{108,112,115} Incomplete resection is associated with substantial risk of recurrence and rarely locally aggressive behavior and death.^{109,116} COX-2 inhibitors may have therapeutic value in large unresectable tumors, a treatment strategy for which only limited anecdotal evidence is available.¹¹⁷⁻¹¹⁹

The long list of competing terms for IMTs attests to its histologic diversity. The most consistent histologic finding is a combination of neoplastic spindle cells and a variably dense infiltrate of polyclonal plasma cells (Fig. 56-17). Immunohistochemical and ultrastructural studies show that the spindle cells have features of myofibroblasts, including expression of smooth muscle-associated proteins. ALK1, a tyrosine kinase receptor, is expressed in between a third and a half of lung tumors, is more frequent in young patients,^{109,120-122} and reflects the observation that *ALK* is fused to a variety of constitutively activated genes via balanced translocations (see later).^{123,124} Interestingly, absence

Figure 56-16 Inflammatory myofibroblastic tumor (IMT). Large IMT in a 21-year-old man in whom an intrathoracic mass was first detected at the age of 10. **A**, CT shows a large mass filling the right hemithorax with heterogeneous attenuation and calcification. **B**, Photograph of right pneumonectomy specimen shows a large mass that, despite its size, was well circumscribed without invasion beyond lung parenchyma.

Figure 56-17 Inflammatory myofibroblastic tumor. High-magnification photomicrograph from the tumor illustrated in Figure 56-16. Neoplastic spindle cells are associated with a prominent infiltrate of plasma cells. Nonneoplastic respiratory epithelium (upper left) is surrounded by neoplastic spindle cells, resulting in a biphasic appearance, a common phenomenon in benign or low-grade nonepithelial tumors. (H&E stain; original magnification $\times 400$.)

of ALK expression may be associated with a greater risk for aggressive behavior.^{109,125}

Although the name suggests a nonneoplastic inflammatory tumor, IMTs are actually low-grade neoplasms. Various techniques have identified a range of genetic abnormalities consistent with the neoplastic nature of IMTs.^{121,123,124,126-128}

The most consistent molecular alteration is a balanced translocation of the *ALK* gene locus (2p23). Fusion of a silent gene (*ALK*) with one of several constitutively expressed genes (e.g., *TPM3*, *TPM4*, *CLTC*) results in aberrant expression of the silent gene that then typically functions as an oncogene. A similar role for *ALK* gene fusions is observed in anaplastic large cell lymphomas and lung adenocarcinoma. The *ALK* inhibitor crizotinib has been used successfully to induce at least a partial response in a patient with IMT bearing an *ALK* rearrangement.¹²⁵ The role of human herpesvirus 8 in the pathogenesis of IMT is controversial and uncertain.¹¹³

SOLITARY FIBROUS TUMOR

Solitary fibrous tumors (SFTs), formerly referred to as *localized fibrous mesotheliomas*, are mesenchymal neoplasms that frequently arise from the pleura. SFTs are not unique to the pleura, however, and have been described in the parenchyma of the lung (*intrapulmonary SFT*), in the mediastinum, and in numerous extrathoracic sites.¹²⁹⁻¹³³

Pleural and intrapulmonary SFTs affect men and women equally.¹³⁴⁻¹³⁹ Mean age at diagnosis is the sixth decade of life. Just more than half of patients are symptomatic with presenting complaints that include chest pain (25%), shortness of breath (15%), and/or cough (12%), attesting to the often large size of these tumors.^{135,136,138,140}

Clubbing is present in about 2% of patients. A paraneoplastic syndrome of hypoglycemia is rare and results from tumor production of insulin-like growth factor.^{36,141-144} Imaging studies show large intrathoracic masses with an average maximum diameter of between 8.5 and 10.5 cm.^{135,136,139,140,145} Chest imaging studies show a lobulated and sharply marginated mass with a broad base abutting the chest wall, frequently associated with compression of surrounding structures (Fig. 56-18, see eFigs. 56-7 through 56-11 and Video 56-2).^{145,146} Heterogeneous attenuation and heterogeneous enhancement are characteristic (see eFig. 56-7 and 56-9).¹⁴⁵ Calcifications are rare. Most pleural and intrapulmonary SFTs behave as benign neoplasms. Patients with histologically benign tumors are cured with complete surgical excision. A more aggressive course is seen in just over 10% of patients and is limited to those who either undergo incomplete surgical excision or have histologically malignant tumors (*malignant SFT*, see eFigs. 56-12 and 56-13).^{134-136,138-140,147}

SFTs are three times more likely to arise from visceral than parietal pleura (see eFig. 56-11). Those arising from visceral pleura are frequently pedunculated and attached to the lung surface by a connective tissue pedicle (Fig. 56-19). Occasional examples arise within the fissures, resulting in a radiologic appearance difficult to separate from an intrapulmonary tumor (see eFig. 56-11). Parietal pleural lesions are more commonly sessile with a broad base of attachment to chest wall, diaphragm, or mediastinum. Histologically, SFTs are variably cellular spindle cell neoplasms with a

Figure 56-18 Solitary fibrous tumor (SFT). CT shows a large benign SFT arising from the visceral pleura with nearly complete atelectasis of the left lung. Together, SFT and inflammatory myofibroblastic tumor are the most likely diagnoses in patients who present with large benign intrathoracic tumors.

Figure 56-19 Solitary fibrous tumor (SFT). Photograph of a resected SFT arising from the visceral pleura. **A**, As demonstrated in this example, most visceral pleural SFTs are attached to the lung by a pedicle and are characterized by a smooth glistening surface (*right*) and an encapsulated homogeneous cut surface without necrosis (*left*). **B**, Less commonly, SFT arises within the fissures as illustrated in this bilobectomy specimen.

collagenous stroma. Malignant variants are larger, more likely to have an invasive growth pattern, and more cellular with associated cytologic atypia, increased mitotic rates, and necrosis.¹³⁵

Recent discovery of recurrent *NAB2-STAT6* gene fusions in solitary fibrous tumors provides a genetic signature helpful in separating SFT from other intrathoracic spindle cell neoplasms.^{147a} Commercially available antibodies for *STAT6* provide a useful diagnostic tool for routine clinical practice.^{147b}

Figure 56-20 Multiple meningothelial-like nodules. Also called diffuse pulmonary meningotheliomatosis, the multiple nodules are shown in a surgical lung biopsy from a 56-year-old woman who presented with dyspnea. **A**, At low magnification, multiple nodules are seen randomly distributed throughout the biopsy. (H&E stain; original magnification $\times 20$.) **B**, At higher magnification, the nodules comprise bland meningothelial cells arranged in poorly formed nests and expanding the interstitium. (H&E stain; original magnification $\times 400$.)

MENINGOTHELIAL-LIKE NODULES AND INTRAPULMONARY MENINGIOMA

Pulmonary *meningothelial-like nodules* (MLNs), historically termed *chemodectomas*, present in less than 5% of autopsies but are frequently seen as incidental findings in surgical specimens from adults.¹⁴⁸⁻¹⁵² MLNs are more common in women and are seen with greater frequency in patients with chronic lung diseases, including chronic interstitial pneumonias and thromboembolic disease.¹⁵⁰ A rare syndrome of multiple bilateral MLNs (*diffuse pulmonary meningotheliomatosis*) has been described in women who present in the sixth to eighth decade of life with multiple nodules seen on CT (see [eFig. 54-28](#)).^{153,154} Half complain of dyspnea and/or cough at presentation. Microscopically, MLNs are composed of nests of epithelioid cells that are histologically and immunophenotypically indistinguishable from meningothelial cells of the central nervous system ([Fig. 56-20](#)). Despite this unexplained phenotypic overlap, molecular studies demonstrate significant differences between MLNs and conventional central nervous system meningiomas.¹⁵³

Primary *intrapulmonary meningiomas* are rare solitary lesions that are unrelated to MLN.¹⁵⁵⁻¹⁵⁷ Men and women are affected equally and present at an average age of 56 years with asymptomatic solitary nodules averaging 3 cm in greatest dimension. Patients with multiple lesions should be presumed to have metastatic disease from a central

Figure 56-21 Granular cell tumor. Photograph demonstrates the cut surface of pneumonectomy specimen in which a granular cell tumor (arrows) partially obstructs the lower lobe bronchus.

nervous system primary until proven otherwise.¹⁵⁸ PET scanning in one series demonstrated uptake consistent with a pulmonary neoplasm.¹⁵⁹ Complete surgical resection is curative in patients with histologically benign meningiomas.

MISCELLANEOUS

Granular cell tumors, referred to in older literature as *granular cell myoblastomas*, are uncommon primary lung neoplasms that typically present as pedunculated or sessile endobronchial tumors (Fig. 56-21, see eFig. 56-14).^{160,161} Lesions are multiple in a fourth of patients. Symptoms are reported in half and result from airway obstruction. Peripheral lung nodules are rare. Pulmonary GCTs are benign and can usually be managed with conservative excision.

Clear cell ("sugar") tumors are rare primary lung tumors that invariably present as asymptomatic solitary lung nodules.¹⁶² Histologic, ultrastructural, and immunophenotypic features are indistinguishable from PEComas and renal angiomyolipomas, a family of neoplasms derived from *perivascular epithelioid cells* (PEC) and related to muta-

tions of the tuberous sclerosis complex genes that affect regulation of the *mammalian target of rapamycin* (mTOR) pathway.^{163,164}

SUMMARY

Benign lung tumors are uncommon but frequently present challenges in diagnosis and management. They comprise a diverse group of epithelial and nonepithelial neoplasms that may present as symptomatic endobronchial lesions or asymptomatic solitary peripheral nodules. Some may become large enough to cause symptoms by compression or displacement of intrathoracic structures. Surgical resection is frequently required for diagnosis and is usually curative.

Key Points

- Benign lung tumors can arise from all cell types within the lung.
- With few exceptions, clues as to the benign nature of the nodules are often lacking on radiographic images and, contrary to expectations, PET scans may also be positive.
- Fat density or specific benign patterns of calcification on imaging are the exceptions that can suggest a benign diagnosis.
- Rare inflammatory myofibroblastic tumors may be associated with *ALK* gene rearrangements that respond to crizotinib.

eFigure 56-1 Squamous papilloma of the trachea. Axial chest CT displayed in lung (A) (see [Video 56-1A](#)) and soft tissue (B) windows shows a multilobulated tracheal lesion (arrowheads). C–E, Sagittal images show the lesion (arrowheads) residing along the posterior tracheal wall. Coronal CT images displayed in lung (F) and soft tissue (G) windows show the tracheal lesion (arrowheads) arising from the posterior and right lateral wall (see [Video 56-1B](#)). H and I, Bronchoscopic images show a multilobulated posterior tracheal lesion; biopsy confirmed squamous papilloma. (Courtesy Michael Gotway, MD; case by Allen Thomas, MD, Veterans Affairs Medical Center, Phoenix, AZ.)

eFigure 56-2 Micronodular pneumocyte hyperplasia in a patient with tuberous sclerosis-lymphangioleiomyomatosis complex. Axial chest CT displayed in lung windows shows several thin-walled cysts (*arrowheads*) associated with small, nonspecific lung nodules (*arrows*), the latter representing micronodular pneumocyte hyperplasia. (Courtesy Michael Gotway, MD.)

eFigure 56-3 Sclerosing hemangioma. Axial enhanced chest CT shown in lung (**A**) and soft tissue (**B**) windows shows a nonspecific, enhancing, circumscribed right middle lobe nodule (*arrowhead*) proven on resection to represent sclerosing hemangioma. (Courtesy Michael Gotway, MD.)

Figure 56-4 Endobronchial hamartoma. **A**, Frontal chest radiograph shows right lower lobe collapse, evidenced by medial and inferior retraction of the right major fissure (*arrowheads*). Right lung volume is diminished overall compared with the left. Axial unenhanced chest CT scans displayed in lung (**B–D**) and soft tissue (**E–G**) windows shows a solid lesion residing within the bronchus intermedius (*arrowheads*, **B**, **E**, and **F**). Right lower lobe collapse (*double arrowheads*, **C**, **D**, and **G**) is present. **H**, Axial high-resolution CT shows hyperexpansion of the right middle lobe, partially compensating for the right lower lobe collapse.

Continued

eFigure 56-4, cont'd **I** and **J**, Coronal chest CT images show the endobronchial lesion (*arrowhead*) within the bronchus intermedius and the right lower lobe collapse (*double arrowheads*) to advantage. **K** and **L**, Axial fused PET-CT images show no significant tracer accumulation within the bronchus intermedius lesion (*arrowhead*) or the collapsed right lower lobe (*double arrowheads*). **M** and **N**, Bronchoscopic images before (**M**) and after (**N**) treatment show decrease in size of the lesion, shown on biopsy to represent hamartoma. (Images courtesy Andrew H. Goldstein, MD.)

eFigure 56-5 Tracheal inflammatory myofibroblastic tumor. T1-weighted axial MR images before (A) and after (B) intravenous gadolinium administration show an irregular lesion (arrowheads) arising from the right lateral tracheal wall. C, Axial T2-weighted MR image shows high signal within the lesion (arrowhead), consistent with fluid density. Biopsy showed inflammatory myofibroblastic tumor. (Courtesy Michael Gotway, MD.)

eFigure 56-6 Inflammatory myofibroblastic tumor. A, Frontal chest radiograph shows a circumscribed nodule (arrow) projected over the right hilum. Axial contrast-enhanced chest CT displayed in lung (B) and soft tissue (C) windows shows a finely lobulated superior segment right lower lobe nodule. Small satellite nodules were present more inferiorly. The appearance of the lesion is nonspecific. Biopsy showed inflammatory myofibroblastic tumor. (Courtesy Michael Gotway, MD; case by Paul J. Conomos, MD, Arizona Pulmonary Specialists, Phoenix, AZ.)

eFigure 56-7 Solitary fibrous tumor of the pleura. Coronal (A) and axial (B) contrast-enhanced chest CT shows an enhancing lesion with extensive mediastinal pleural contact (arrow), suggesting an extrapulmonary origin (see [Video 56-2](#)). C, Axial T1-weighted MR image before intravenous contrast administration. D, Axial contrast-enhanced 3D spoiled fast gradient echo image shows extensive lesion enhancement (arrow). Surgical resection proved solitary fibrous tumor of the pleura. (Courtesy Michael Gotway, MD.)

eFigure 56-8 Solitary fibrous tumor of the pleura. Unenhanced (A) and contrast-enhanced (B) chest CT shows the typical appearance of an extrapulmonary lesion (arrows): a circumscribed, lenticular- or oblong-shaped opacity creating obtuse margins with the chest wall. Surgical resection proved solitary fibrous tumor of the pleura. (Courtesy Michael Gotway, MD.)

eFigure 56-9 Solitary fibrous tumor of the pleura; large. A, Frontal chest radiograph shows near complete opacification of the left thorax with slight shift of the cardiomeastinal structures to the contralateral side. B–D, Axial contrast-enhanced chest CT shows a solid, vascularized lesion occupying much of the left thorax. The large size of the lesion makes determination of the organ of origin difficult, but solitary fibrous tumor of the pleura is a consideration, particularly when no overtly aggressive features, such as a large pleural effusion, rib destruction, or lymph node enlargement, are evident. (Courtesy Michael Gotway, MD.)

eFigure 56-10 Solitary fibrous tumor of the pleura. A, Frontal chest radiograph shows a circumscribed mass (arrow) along the left heart border. The mediastinal contact, smoothly margined character of the lesion, and obtuse angles of the lesion at its interface with the lung suggest an extrapulmonary origin. B, Unenhanced chest CT shows the lesion (arrow) has mildly inhomogeneous attenuation and significantly contacts the left mediastinum and pericardium. C, Axial fused PET-CT image shows little tracer accumulation within the lesion (arrow); note the similarity in tracer uptake between the lesion (arrow) and mediastinal blood pool in the aorta (arrowhead). Surgical resection proved solitary fibrous tumor of the pleura. (Courtesy Michael Gotway, MD.)

eFigure 56-11 Solitary fibrous tumor of the pleura: visceral pleural origin evident on imaging. **A**, Frontal chest radiograph shows a poorly defined left upper lobe opacity (*arrow*). **B**, Repeat frontal chest radiograph 5 years following **A** shows slow interval growth in the lesion (*arrow*). Axial unenhanced chest CT images displayed in soft tissue (**C**) and lung (**D**) windows shows a homogeneous, circumscribed, noncalcified lesion (*arrow*, **C**). On the lung window image (**D**), the lesion is clearly related to the left major fissure (*arrowheads*). **E**, Specimen following surgical resection was shown to be solitary fibrous tumor of the pleura. (**A–D**, Courtesy Michael Gotway, MD.)

Figure 56-12 Malignant solitary fibrous tumor of the pleura. A–C, Axial contrast-enhanced chest CT shows a large, homogeneous, solid, vascularized left-sided mass with broad pleural surface contact. Biopsy showed features consistent with malignant fibrous tumor of the pleura. (Courtesy Michael Gotway, MD.)

Figure 56-13 Malignant solitary fibrous tumor of the pleura. A and B, Axial contrast-enhanced chest CT displayed in soft tissue windows shows circumscribed and lobulated soft tissue masses (*arrows*) involving the mediastinal and posterior pleural surfaces, proven on biopsy to represent fibrous tumor of the pleura. Axial contrast-enhanced chest CT (C) and axial T2-weighted MRI (D) show lobulated soft tissue masses (*arrowheads*) related to the right mediastinal and posteromedial pleural surfaces, again reflecting fibrous tumor of the pleura. Axial unenhanced chest CT (E) and fused PET-CT image (F) show a metabolically active lesion involving L1, representing metastatic malignant fibrous tumor of the pleura. This patient originally had a right upper thoracic pleural fibrous tumor arising from the pleura resected in 1997. (Images courtesy Diego Ruiz, MD, Palo Alto Medical Clinic, CA.)

Figure 56-14 Granular cell tumor of the trachea. Axial enhanced chest CT (**A** and **B**) and coronal maximum intensity projection (**C**) performed as part of CT aortography in a patient with chest pain shows the incidental detection of a plaque-like lesion (*arrowheads*) along the right lateral tracheal wall. **D**, Bronchoscopic image shows a lobulated lesion corresponding to the CT abnormality. Biopsy proved malignant granular cell tumor. (**A–C**, Courtesy Michael Gotway, MD.)
